The role of perceived social support in the relationship between being bullied and mental

health difficulties in adolescents.

Abstract

The aim of the study was to test the relationship between experiences of being bullied, cyberbullied and mental health difficulties, and whether these relationships are moderated by perceived social support and gender. Data were collected from 3,737 Year 8 pupils (aged 12 and 13 years old; 50.1% male) using an online questionnaire. Measures of bullying victimisation, perceived social support, and mental health difficulties were included in the online questionnaire. Moderation analyses were conducted to test whether the relationships between being bullied, cyberbullied, and mental health difficulties were moderated by perceived social support and gender. Four models were estimated, each assessing a different source of perceived social support (from family, friends and peers, professional sources, and the perception of having no support). Results of these analyses indicated that across all four models being bullied was significantly associated with mental health difficulties, and being cyberbullied was only significantly associated with poorer mental health difficulties in girls in one of the models. The different sources of perceived social support did not moderate the relationship between experiences of being bullied or cyberbullied and mental health difficulties for either boys or girls. However, significant associations were found between a perceived lack of support, perceived social support from friends and family and mental health difficulties in girls, but not in boys. The results contribute to a complex body of research findings exploring the role of perceived social support in the relationship between experiences of being bullied and mental health difficulties.

Being bullied is a frequent experience for many adolescents (Juvonen & Graham, 2014), and one which can relate to mental health difficulties in both the short- and long-term (Ttofi, Farrington, Lösel, & Loeber, 2011). Perceived social support is one factor which may buffer the relationship between experiences of being bullied and mental health difficulties, providing adolescents with resources to draw upon for support. A recent systematic review has highlighted gender differences in the buffering effect of perceived social support, alongside differences on the basis of the source of perceived social support, in the relationship between experiences of being bullied and mental health difficulties (Noret, Hunter, & Rasmussen, 2018). Therefore, the aim of this study is to examine the extent to which different sources of perceived social support moderate the relationship between experiences of being bullied, cyberbullied, and mental health difficulties.

Bullying is a distinct form of aggressive behavior which is experienced repeatedly, over time, and where there is an imbalance of power between those perpetrating the aggression and the recipient, for example on the basis of physical strength or popularity (Olweus, 1999; Whitney & Smith, 1993). The behavior also includes an element of intentionality, defined as the intention on the part of the perpetrator to hurt the target (Olweus, 1978). Bullying can involve directly observable acts, such as verbal (e.g. name calling) or physical aggression (e.g. being hit, kicked, or punched) (Marini, Dane, Bosacki, & YLC-CURA, 2006), and more indirect behaviors (e.g. being left out of a group, or being ignored) (Crick & Grotpeter, 1995). Cyberbullying is defined as bullying which is perpetrated through electronic and communication tools (Campbell, 2005; Hinduja & Patchin, 2008) and can involve both directly observable (e.g. mean and humiliating posts on social media sites) and more indirect behaviors (e.g. blocking someone from an online conversation) (Langos, 2012).

In their recent survey of 120,115 UK adolescents, Przybylski and Bowes (2017) found that 27% of their sample had experiences of being directly and indirectly bullied only. Less than 1% of their participants had experienced being cyberbullied only, and approximately 3% had experienced all three forms of aggression. Similar findings have been reported in a large scale survey of 440,000 US students, where 17.3% of participants reported being verbally bullied, compared to 4.5% of participants who reported being cyberbullied (Olweus & Limber, 2018). Such findings suggest that while many adolescents experience being cyberbullied, other forms of bullying are more commonly reported (Olweus, 2012). While experiences of being bullied and cyberbullied have often been studied separately there have been calls for cyberbullying to be viewed as a form of bullying and one which should be studied as part of a broader 'bullying context' (Olweus & Limber, 2018). Studying both experiences of being bullied and cyberbullied in parallel allows us to understand the unique and combined impact of these different bullying experiences (e.g. Giménez Gualdo, Hunter, Durkin, Arnaiz, Maquilón, 2015).

Adolescence is a time of substantial change in the peer group, involving a transition towards a greater importance of peer-relationships and peer-group status (Bukowski, Hoza, & Boivin, 1993). Being bullied challenges these peer-group goals as the aim of those perpetrating bullying is to demean and humiliate victims in front of the peer group, damaging social reputation and status (Juvonen & Graham, 2014). A number of meta-analyses have demonstrated the relationship between being bullied and mental health difficulties, such as internalizing symptoms of depression and anxiety, and externalizing symptoms such as aggression (Reijntjes, et al., 2011, Reijntjes, Kamphuis, Prinzie, & Telch, 2010). In their recent review, Gini, Card, and Pozzoli (2018), found that both experiences of being bullied and being cyberbullied were independently associated with mental health difficulties. Such relationships have been found in both cross-sectional and longitudinal studies, suggesting

both an immediate and long-term association between being bullied, cyberbullied, and mental health difficulties (Ttofi, Farrington, Lösel, & Loeber, 2011). However, not all those who have been bullied develop mental health difficulties (Newman, Holden, & Delville, 2005). The Transactional Model of Stress (TMS) (Lazarus & Folkman, 1984) offers a possible theoretical framework for examining individual differences in the relationship between victimisation and negative outcomes (Noret et al, 2018; Raskauskas & Huynh, 2015).

The TMS proposes that reactions to stressful situations, such as being bullied, are the product of a process of primary and secondary cognitive appraisal, and the coping strategy employed. Primary appraisals reflect an individual's evaluation of the importance of the event in the context of their own personal goals and beliefs, whereas secondary appraisals reflect an individual's evaluation of the resources they have available to manage the situation (Lazarus & Folkman, 1984). Perceived social support is one form of secondary appraisal and reflects the extent to which individuals believe they are loved and valued and can depend on others for support when faced with stressful or challenging situations (Cobb, 1976; Lakey & Cohen, 2000). The stress buffering hypothesis (Cohen & Willis, 1985) suggests that perceived social support can moderate the relationship between a stressor and negative outcomes, where the relationship will be weaker in those with a high level of perceived support. Cohen and Willis (1985) proposed that this buffering role can function in two ways: it can reduce the perception of threat or risk of harm appraised in a given situation, or it can provide individuals with options to manage and cope with the stressor. Alternatively, the main effect model of perceived social support (Cohen, 2004; Cohen & Willis, 1985), suggests that perceived social support can directly predict positive mental health, even in the absence of any stressful or challenging situations. The perception of having social support provides individuals with the feeling that they are supported and accepted, and have resources available to manage challenging situations (Cohen, 2004).

The perception of domain specific social support reflects the perceived support available from specific individuals (Pierce, Sarason, & Sarason, 1991). From a socio-ecological perspective, in early adolescence, domain specific sources of support may reflect support from family, friends and peers, and teachers. Such individuals are all part of an adolescent's microsystem and are likely to have an important influence on adolescent development (Bokhorst, Sumter & Westenberg, 2009; Pössel et al., 2018). While the importance of peer relationships increases in adolescence (Bukowski et al, 1993), family relationships continue to be an important form of social influence (Desjardins & Leadbeater 2011). Adolescents also spend a great deal of time at school in the presence of teachers and peers. As adolescents develop greater independence and autonomy it may be that these sources of social support are evaluated as important for school related stressors as they offer the opportunity to seek support beyond the family (Yeung & Leadbeater, 2010).

Understanding the social context in which bullying occurs, and the individual predictive relationships of different sources of perceived social support, is important to understand both the unique associations with psychological adjustment, and the development of prevention and intervention activities (Demaray & Malecki, 2003; Pössel et al., 2018). These different forms of domain specific perceived social support have been examined within a bullying context. In their systematic review of this literature, Noret et al. (2018) highlighted that research to date has focused on the moderating (buffering) role of support from particular individuals, specifically parents, teachers, peers/classmates and close friends.

Focusing specifically on perceived social support from adults, in a bullying context perceived social support from teachers and parents tend to be the sources of support most frequently examined. While perceived support from such adults has been found to be protective, gender differences in the literature have been reported. For example, a moderating role for perceived support from a teacher has been found in boys but not girls (Davidson &

Demaray, 2007), whereas Tanigawa, Furlong, Felix, and Sharkey, (2011) found no moderating role for perceived teacher support. Similarly, regarding perceived support from parents/ guardians, contradictory gender differences have been reported. Perceived social support from a parent/ guardian has been found to moderate the relationship between being bullied and adjustment in girls but not boys (Davidson & Demaray, 2007), and separately in boys but not girls (Tanigawa, Furlong, Felix, & Sharkey, 2011), whereas some report no moderating role for parental support (e.g. Cheng, Cheung, & Cheung, 2008; Holt & Espelage, 2007). The ages of participants across these studies spanned across late childhood and adolescence. As adolescents move towards greater independence, this may be reflected in a greater importance placed on other adults in their social network (e.g. teachers) and friends (Bokhorst, Sumter & Westenberg, 2010; Helsen, Vollebergh & Meuus, 2000). Therefore, the different findings reported in these studies may reflect developmental differences in the importance of different forms of perceived support (Pössel, et al., 2018, Noret et al., 2018). Despite the inconsistent findings, those studies reporting a buffering role for parent and/or teacher support found it to be protective, where the relationship between experiences of being bullied and mental health difficulties was weaker for those with greater perceived support in these domains.

In a bullying context, support from friends and peers is the most frequently studied form of domain specific perceived support. Findings from these studies have also yielded inconsistent findings (Noret et al., 2018). Some studies have demonstrated a protective buffering role in boys but not girls (Cheng et al., 2008; Tanigawa et al., 2011) and some studies have demonstrated this finding in girls but not boys (Lim et al., 2011). Others have reported that the relationship between experiences of being bullied and mental health difficulties is *worse* for those with perceived support from friends or peers (e.g. Holt & Espelage, 2007). These inconsistent findings may reflect the different ways in which

perceived social support has been measured, or whether the focus was on perceived social support from peers or from close/ best friends (Chu, et al, 2010; Rueger, Malecki, & Demaray, 2010). Alternatively, these differences may be reflective of the changeable nature of peer relationships and friendships in adolescence (Gariépy, Honkaniemi, & Quesnel-Vallée, 2016).

More recent research suggests that these different forms of domain specific perceived social support can buffer the relationship between experiences of being cyberbullied and mental health difficulties. In their study of perceived support from family, defined as the number of family dinners, Elgar et al. (2014) found that such support moderated the relationship between experiences of being cyberbullied and mental health difficulties. The relationship was weaker in adolescents who reported a higher number of family dinners. Wright (2017) has also demonstrated the relationship longitudinally in her study of 131 pupils with developmental disorders: perceived social support from parents and teachers moderated the relationship between experiences of being cyberbullied and depressive symptomology measured one year later. Such research supports a stress buffering role for perceived social support in the relationship between experiences of being bullied and mental health difficulties.

Although limited, there is evidence suggesting differences in the role of domain specific forms of perceived social support in the relationship between different forms of bullying experiences and mental health difficulties (e.g. Yeung & Leadbeater, 2010). Different forms of perceived social support may be perceived as more or less helpful depending on the nature of the bullying experienced. Adolescents may be cautious about seeking help from the perceived support available for fear of any negative reactions, such as parents' overreaction (deLara, 2012), teachers not responding appropriately or their intervention making the situation worse (Bourke & Burgman, 2010), or help seeking

resulting in further peer-rejection (Cowie, 2011). The usefulness of perceived social support in managing experiences of being cyberbullied may also be evaluated differently to experiences of being bullied more generally, particularly with regard to perceived social support from adults. Adolescents may fear that parents will overreact which may result in a loss of access to technology and social media (Mishna, Saini, & Solomon, 2009). Alternatively, adolescents may perceive that support from adults may be unhelpful due to their perception that adults have a limited understanding of cyberspace and technology (Machmutow, Perren, Sticca, Alsaker, 2012).

The current study

Research to date has reported mixed findings regarding the relationship between experiences of being bullied, cyberbullied, perceived social support, and mental health difficulties. Such research suggests that there may be gender differences in this relationship (e.g. Lim et al., 2011), and that perceived social support may not always be protective (e.g. Holt & Espelage, 2007). Despite suggestions that experiences of being cyberbullied should be studied alongside experiences of other forms of bullying (Olweus & Limber, 2018) and evidence that being cyberbullied is associated with mental health difficulties independently of other forms of bullying (Gini, Card, & Pozzoli, 2018), much of the research exploring the role of perceived social support has tended to measure either experiences of being bullied or cyberbullied, and has tended to measure only one form of perceived support. Furthermore, no studies have examined the role of different forms of perceived social support in the relationship between experiences of being cyberbullied and mental health difficulties.

The current study will build upon previous research, and address some of the limitations identified, to test for gender differences in the role of domain specific forms of perceived social support in the relationship between both experiences of being bullied and cyberbullied, and mental health difficulties. Specifically, the following research questions

will be addressed: 1) Is there a gender difference in the experience of being bullied, in perceived social support, and in symptoms of mental health difficulties? 2) Are experiences of being cyberbullied and being bullied significantly associated with mental health difficulties? 3) Does the perception of having no social support moderate the relationship between being bullied and cyberbullied and mental health difficulties? 4) Does perceived social support from family, peers, and/or professionals moderate the relationship between being bullied and mental health and being cyberbullied and mental health difficulties? 5) Does gender moderate the relationships between experiences of being bullied, cyberbullied, perceived social support and mental health difficulties?

Method

Design and Participants

A cross-sectional survey design was employed. Participants were 3,737 Year 8 pupils, 50.1% were male (N=1,873), 48.4% were female (N=1,807), and 1.5% (N=57) did not report their gender. All pupils were year 8 pupils (equivalent to 7th grade in the US school system) and were aged 12 and 13 years old. As year 8 pupils, participants were in their second year of secondary school education. Participants were recruited over three academic years (2012-2014) from 10 secondary schools within one local authority region in the North of England.

Measures

The current study is based on the secondary data analysis of data collected through a Local Education Authority (LEA) project examining the experiences of being bullied and general wellbeing of children and young people in local primary (Elementary schools in the US) and secondary schools (Junior High School in the US). The project involved consultation with LEA representatives, head-teachers, educational psychologists and representatives from the police. The questionnaire examined general experiences at school, experiences of being bullied, bullying others, and witnessing bullying at school, alongside reports of current worries, concerns, perceived social support and mental health difficulties. The questionnaire took pupils approximately 30 minutes to complete. Of interest to this study were participants' reports of being bullied, their perceived social support, and their responses to the measure of mental health difficulties.

Experiences of being bullied.

Pupils were presented with the following definition: *Being bullied means that you have been intentionally hurt (meaning someone did it on purpose) and that you were hurt by one person or a group of people more than once.* The definition was developed in consultation with the LEA to reflect how bullying was discussed with pupils in the local

schools. Pupils were then presented with a list of thirteen behaviors and asked to report on how often in the past month they had experienced the behaviors. These behaviors were based in part on the Olweus Bully/Victim Questionnaire (Solberg & Olweus, 2003) and included the addition of items related to the experience of cyberbullying. The list included three examples of physical bullying, (*been hit or kicked or punched; threatened with being hurt; been frightened by a look or stare*) one item related to verbal bullying (*been called names, or been insulted),* three examples of relational bullying (*been ignored by others; had rumours spread about you; been left out of a group),* five cyberbullying items (*received nasty text messages; received nasty emails; been blocked from an online conversation; had something hurtful posted on a social networking site; had someone post an embarrassing photo or video of you on a website)*, and an item relating to being bullied in *other ways.* Pupils were asked how often they had experienced each of the behaviors in the past month on a five-point likert scale, ranging from *This hasn't happened to me in the past month* (1) to *At least once a day* (5)*.* As the scale was designed for the purposes of the study it was unclear how items would cluster together. Therefore, an exploratory factor analysis (maximum likelihood) using direct oblimin rotation was conducted using SPSS. The analysis yielded a two factor model, identified through the scree plot and rotated component matrix, with items clustering around two factors: experiences of being bullied and experiences of being cyberbullied. The two factors accounted for 57.33% of the variance, with bullying accounting for 45.87% and cyberbullying accounting for a further 11.46%. Both factors had eigenvalues greater than one; bullying = 5.51, cyberbullying =1.38. The internal reliability of both scales was good, for bullying α=.84, and for cyberbullying α=.85. Items were meaned to create scores ranging from 1 to 5, with higher scores indicating more frequent experiences of being bullied.

Perceived social support.

A measure of perceived social support was developed in collaboration with the LEA. The measure was similar to other categorical measures of perceived social support in that pupils were provided with a list of possible sources of support (e.g. Rigby & Slee, 1999; Sarason, Levine, Basham, & Sarason, 1983). But rather than ask participants about the amount of support available, the measure asked pupils whether they could or could not seek support from the different sources of support presented. Pupils were presented with the following instruction: *If you were in trouble or were concerned about something who would you confide in (who would you talk to), please select all the answers that apply to you.* Pupils were then presented with a list of 17 possible sources of support clustering around four domains, including having no-one to talk to, sources of family support (*parent or person who looks after me, brother or sister; aunt, uncle or cousin, grandparents or grandparent*), sources of friend/ peer support (*friend; boyfriend or girlfriend, older pupil*), and sources of professional support (*a teacher; non-teaching staff at school; school nurse; school counsellor; chaplain; PSHE co-ordinator; youth worker; peer-mentor*). The question also included an *other* option, however this was not included in the analysis.

For each item, pupils indicated whether they felt they could talk to each person (coded as yes=1), or no they could not talk to that person (no=0). For the purposes of this study, the individual sources of supported were grouped to represent sources of support from family, friends and peers, and professional support. Responses were coded as to whether participants did (=1) or did not have access (=0) to support from family, from teachers, and/or from professional sources. The item related to having no-one to talk to was analysed separately and coded differently. This item was coded as 1 = having no one to talk to, and 0 = having someone to talk to.

Mental Health Difficulties.

Mental Health difficulties were measured using the short 12-item version of the General Health Questionnaire (GHQ-12) (Goldberg & Williams, 1988). Pupils were presented with a list of 12 statements reflecting different thoughts and feelings (e.g. *lost much sleep over worry?*) and were asked how often they felt that way in the past month. Responses to the 12 statements were rated on different four-point likert scales, to capture the severity of distress (Tait, Hulse, & Robertson, 2002). Item 1 was rated on a four-point scale from *better than usual* (1) to *much less than usual* (4)*, items 2 to 7 were rated on a four-point scale from *not at all* (1) to *much more than usual* (4), and items 8 to 12 were rated on a four-point scale from *more so than usual* (1) to *much less than usual* (4)*. Responses to items are then meaned to create a score from 1 to 4, a lower score reflects a lower experience of mental health difficulties (and so better mental health), higher scores indicate a more frequent experience of mental health difficulties. The GHQ-12 has been found to have good internal reliability and has previously been used with adolescent samples to measure mental health difficulties (Baksheev, Robinson, Cosgrave, Baker, & Yung, 2011). In the current study, the internal reliability of the scale was good (Cronbach's α=.91).

Procedure

The study was approved by the University's research ethics committee. The survey was administered online using the SurveyMonkey online survey tool. Schools were recruited with support from the LEA during an annual briefing session. All secondary schools in the area (N=10) participated in the study annually over the three-year period, with data being collected from a different cohort of year 8 pupils every year. To ensure consistency in the administration of the survey, schools were provided with a list of standardized instructions and a presentation file. Schools then administered the survey to their pupils in a designated lesson, in exam conditions. Data collection occurred at the same point every year, in the summer term (June/ July).

Data Analysis

Moderation analyses were conducted using MPLUS (v7.31 MAC). Results were downloaded from the SurveyMonkey tool and the GHQ, bullying, and cyberbullying scales were calculated using SPSS (V24). Continuous predictors were mean centred before interaction terms were created. Moderation analyses were conducted using maximum likelihood with robust standard errors estimation (MLR) to account for the categorical nature of the moderators (the sources of perceived social support and gender). The analyses were conducted using Full Information Maximum Likelihood (FIML) to account for missing data.

An initial model was calculated including the main effects of experiences of being bullied, being cyberbullied, all sources of perceived social support, and where gender and all sources of perceived social support (except having no-one to talk to) were entered as moderators. Variance inflation factors (VIF) and tolerance statistics were calculated to identify any issues with multicollinearity. In this initial model, the levels of multi-collinearity exceeded acceptable limits (VIF>5) (Akinwande, Dikko, & Samson, 2015), with VIF values ranging from 7 to 12. To address this, four separate models were calculated, one for each source of support, see figure 1. The measure of social support was entered as a moderator in each model, and the multi-groups method was used to test for the moderating role of gender. The Satorra-Bentler rescaled chi-square test was used to compare the models for boys and girls, individual z tests were also used to test for gender differences in unstandardized regression coefficients (Paternoster, Brame, Mazerolle, & Piquero, 1998).

FIGURE 1 ABOUT HERE

When reporting the results of the moderation analysis, both unstandardized and standardized path co-efficients are presented. For continuous predictors (experiences of being

bullied and cyberbullied) standardized paths are calculated based on the standard deviations of both the predictor (x) and outcome variables (y) (STdyx in MPlus) (Muthén & Muthén, 2017). For categorical predictors (sources of social support), standardized paths are calculated on the basis of the standard deviation of the outcome variable, and are interpreted as a standard deviation change in the outcome variable as the predictor variable changes from 0 to 1 (STdy in MPLUS) (Muthén & Muthén, 2017).

RESULTS

Is there a gender difference in the experience of being bullied, in perceived social support and symptoms of mental health difficulties?

Experiences of being bullied, cyberbullied, and mental health difficulties.

As shown in Table 1, participants reported experiencing bullying more often than cyberbullying. There were significant correlations between being bullied and being cyberbullied. Significant correlations were also found between both being bullied and being cyberbullied and mental health difficulties.

TABLE 1 ABOUT HERE

Table 2 shows the descriptive statistics and correlations, presented separately for boys and girls. Girls reported experiencing being bullied and cyberbullied more than boys. Scores of mental health difficulties were also higher in girls than boys. Significant positive correlations between experiences of being bullied, cyberbullied and mental health difficulties were found in both boys and girls. Gender differences in mental health difficulties, experiences of being bullied and being cyberbullied scores were analysed using independent t-tests. Significant differences and small effects in mental health difficulties and experiences of being cyberbullied scores were found. In both cases girls reported higher scores than boys. No significant differences were found in scores of being bullied.

TABLE 2 ABOUT HERE

Perceived social support

The sources of support participants reported having available are show in Table 3. Overall, 11.6% of the sample reported having no-one to talk to. Support from family was more frequently reported than professional support or support from friends/ peers. Chi-square analyses were used to test the association between gender and the different sources or perceived social support. There was a significant association, and small effect, between

gender and having no-one to talk to, a higher proportion of boys reported having no-one to talk to. Significant associations and small effects were also found between gender and talking to family, and between gender and talking to friends and peers. A higher proportion of girls reported being able to talk to family or friends/ peers. No significant association was found between gender and professional support. The proportion of boys and girls who reported being able to access professional support was approximately equal.

<div align="center">**TABLE 3 ABOUT HERE**</div>

Are experiences of being cyberbullied and being bullied significantly associated with mental health difficulties?

The four models accounted for between 24% and 25% of the variance in mental health difficulties (R^2=.24 to .25) for girls, and for boys between 11% and 12% of the variance (R^2=.11 to .12). Across all four models, for both boys and girls, being bullied was significantly associated with mental health difficulties. Being cyberbullied was significantly associated with mental health difficulties for girls in only one model (model 4: assessing perceived support from professional sources).

Does perceived social support moderate the relationship between experiences of being bullied and mental health and between being cyberbullied and mental health difficulties?

As show in table 4, across all four models no source of support moderated the relationship between experiences of being bullied or cyberbullied and mental health difficulties in either boys or girls.

Does gender moderate the relationships between experiences of being bullied, being cyberbullied, perceived social support and mental health difficulties?

The moderating role of gender was examined using the multigroups method of testing for moderation, using Satorra-Bentler tests. Gender moderated the relationships in the no

social support model, SBχ^2 (df=5) = 20.37, p=.001. A significant gender difference was found in the path between having no one to talk to and mental health difficulties, Z=-2.33. Having no-one to talk to was significantly associated with mental health difficulties in girls (b=.16) but not boys (b=.004). Gender was also found to moderate associations in the family support model, SBχ^2 (df=5) = 13.93, p=.020. A significant gender difference was found in the association between perceived support from family and mental health difficulties; Z=2.00, this source of support was significantly associated with fewer mental health difficulties in girls (b=-.15) but not in boys (b=-.05). Gender significantly moderated the relationships in the friend support model, SBχ^2 (df=5) = 11.65, p=.040. The association between being able to talk to friends/ peers was significantly associated with mental health difficulties in girls (b=.07) but not boys (b=.04); however, no significant difference in the path between perceived support from friends/ peers and mental health difficulties (Z=-.83), or in any of the other paths was found. Gender did not moderate the relationships across variables in the professional support model, SBχ^2 (df=5) = 17.46, p=.071.

TABLE 4 ABOUT HERE

DISCUSSION

The aim of the current study was to examine the role of perceived social support in the relationship between experiences of being bullied, cyberbullied, and mental health difficulties, and whether this was moderated by gender. Being bullied was significantly associated with mental health difficulties across all four models. Of the four models, experiences of being cyberbullied was only directly associated with mental health difficulties in the model assessing perceived support from professional sources. Perceived social support from friends/peers, parents and the perception of having no-one to talk to were associated with mental health difficulties in girls but not boys. No source of perceived social support moderated the relationships between being bullied or being cyberbullied and mental health difficulties, in either girls or boys.

Consistent with previous research (e.g. Przybylski & Bowes, 2017), experiences of being bullied were more frequently reported than experiences of being cyberbullied by both boys and girls. The prevalence of being bullied was similar in boys and girls, however reports of being cyberbullied were significantly higher in girls. This finding is consistent with some previous studies (e.g. Rivers & Noret, 2010; Study 1 in Smith, Mahdavi, Carvahlo, Fisher, Russell, & Tippett, 2008); however, gender differences in experiences of being cyberbullied are inconsistent in the research literature (Tokunaga, 2010). The gender difference in experiences of being cyberbullied identified in the current study may be due to different usage in early adolescence. Gender differences have been reported in a number of studies, where boys typically report engaging in more gaming activities, and girls report greater use of social media (Houghton, Hunter, Rosenberg, Wood, Zadow, Martin, & Shilton, 2015; Rosenberg, Houghton, Hunter, Zadow, Shilton, Wood, & Lawrence,

2018). The measure used in the current study focuses on cyberbullying which occurred through social media (e.g. being left out of an online conversation or having a humiliating/ embarrassing picture taken) or through mobile phone (e.g. nasty text messages) but did not include any reference to bullying which occurs through online games. Recent research has identified this as a common experience in online games, and more frequently experienced by boys (e.g. Lee & Shin, 2017). Future research should include online gaming in any measure of cyberbullying.

Across all models being bullied was associated with mental health difficulties for both boys and girls. The Transactional Model of Stress (Lazarus & Folkman, 1984) suggests that for an experience to be deemed stressful and lead to negative outcomes, it must first challenge particular goals held by the individual. Developing close and intimate friendships is a major developmental goal in early adolescence (Berndt, 1982). Experiences of being bullied challenges such goals, by damaging friendships and social relationships (Juvonen & Graham, 2014) which can subsequently lead to mental health difficulties. Unlike other research (e.g. Gini, Card, & Pozzoli, 2018), no independent association was found between experiences of being cyberbullied and mental health difficulties, except in model four (the professional support model). Some forms of cyberbullying are very public, this visibility may result in others intervening and supporting the victim (Slonje, Smith, & Frisén, 2017), providing strategies for coping with the cyberbullying before it begins to impact on mental health difficulties. In a professional context, it may be that professionals working with young adolescents may not be witness to the experiences or may not be able to effectively stop cyberbullying, which may lead to a continuation of the behavior and subsequent impact on mental health difficulties. This different pattern of associations between bullying, cyberbullying and mental health difficulties

reported in this study highlights the importance of studying experiences of being cyberbullied in a broader bullying context rather than in isolation (Olweus and Limber, 2018).

The findings of this study also highlight gender differences in adolescents' perceptions of available support. More boys reported having no one to talk to about their worries and concerns compared to girls. Consistent with previous research (e.g. Furman & Buhrmester,1992), girls were significantly more likely to report perceived support from friends/peers. Girls were also more likely to report support from parents and teachers. There was no significant gender difference in the perception of available professional support. The gender differences in the perception of available support, may reflect the nature of girls' social relationships in early adolescence. Compared to boys, girls are more likely to seek out intimacy and closeness in relationships, and are more likely to spend time developing such relationships (Rueger et al, 2010). Such gender differences in the development of social relationships in early adolescence may explain the difference in perceptions of available support reported in this study.

Gender differences were also found in the relationship between perceived social support and mental health difficulties. None of the sources of support were associated with mental health difficulties for boys. The gender differences in the perception of available support may reflect gender differences in the importance of social relationships in early adolescence or gender differences in coping styles (Rueger, Malexki, & Demaray, 2010). In girls, the perception of having no one to talk to, and the perception of support from friends/peers, were both significantly associated with mental health difficulties while perceived social support from parents was significantly associated with fewer mental health difficulties, and therefore better mental health. Similar to more global measures of perceived social support, the

perception of having no one to talk to may result in the perception of not being valued or supported, or isolated and vulnerable which may directly impact on mental health difficulties (Stice, Ragan, & Randall, 2004). The different pattern of associations for perceived support from family, and perceived support from friends and peers, reflects findings from the broader literature on the relationship between perceived social support and depression (e.g. Stice, Ragan, & Randall, 2004). The perception of support from parents, and family more broadly may be more valuable as such support is more consistent. Parents and older family members may be better equipped to provide more valuable support and better guidance based on their life experience (Stice, Ragan, & Randall, 2004).

From a TMS perspective, as a form of secondary appraisal, perceived support from family may be evaluated as more important and useful as a reflection of the better guidance and support previously received. The association between perceived support from friends/ peers and mental health difficulties may reflect the instability and changeable nature of the peer group, particularly in early adolescence (Stice, Ragan, & Randall, 2004). This finding may reflect the evaluation of previous support sought from friends or the broader peer group. It may be that the support has not been helpful in the past (Hodges, Boivin, Vitaro, & Bukowski, 1999), or that friends or peers have minimised the experiences (Camara, Bacigalupe, & Padilla (2017). Alternatively, if adolescents repeatedly seek support from friends/ peers this may result in support erosion (Slavin & Rainer, 1990), or rejection from the peer group (Rueger, Malecki, Pyun, Aycock, & Coyle, 2016). Understanding changes in the perception of available social support in relation to peer relationships is needed to better understand the relationship between this form of perceived social support and mental health difficulties.

Although perceived social support was associated with mental health
difficulties in girls, it did not moderate the relationship between experiences of being
bullied or cyberbullied and mental health difficulties, in either boys or girls.
Therefore, the results of all four models lend support to the main effect model of
perceived social support (Cohen, 2004) rather than the stress buffering hypothesis
(Cohen & Willis, 1985). A similar finding was reported by Rigby (2000), who
suggested that while perceived social support did not moderate the relationship
between victimisation and mental health difficulties, it may be that a mediation model
may offer a better explanation of the relationship. Being bullied is a unique stressor,
in that the aim of this behavior is to damage social relationships and reputation
(Juvonen & Graham, 2014). Over time, as experiences of being bullied continue, it
may be that social relationships are damaged, leaving those being victimised to feel
isolated or struggle to develop social relationships (Rigby, 2000). Future longitudinal
research is required to better understand the relationship between being bullied,
perceived social support and mental health difficulties to examine how continued
experiences of being bullied damages peer networks and the perception of available
support.

Limitations and future directions

The findings of this study contribute to a complex and inconsistent body of
research findings examining the role of perceived social support in the relationship
between experiences of being bullied and mental health difficulties. A strength of our
study is that it investigated both experiences of being bullied and cyberbullied and the
role of a number of different sources of perceived social support, in a large
representative sample of 13- and 14- year olds. This approach to measurement

24

enabled us to identify different associations between different forms of bullying, and different forms of perceived social support.

The data were however collected using self-report measures, which can be challenging for both bullying victimisation and perceived social support. Identifying the prevalence of being bullied can vary due to methodological inconsistencies related to the way in which respondents are asked about their experiences. Reports of having experienced being bullied can vary due to the time frame provided, and whether a definitional or behavioral approach has been taken (Olweus & Limber, 2018; Volk, Veenstra, & Espelage, 2017). In an attempt to manage these challenges, pupils were provided with a definition that was already used with pupils in schools in the LEA and also provided with a list of behaviors, to address the limitations associated with single item questions on bullying. However, the data collection was dependent on self-report, which may be affected by social desirability (Solberg & Olweus, 2003). As such future research could consider employing the use of peer or teacher nominations to supplement the self-report data (Solberg & Olweus, 2003).

Similarly, the challenges associated with measuring perceived social support are well documented, and may explain the inconsistencies in research findings (Rueger, Malecki & Demaray, 2010). In the current study we measured perceived social support by focusing on who participants could talk to if they were worried or concerned about something. This approach enabled us to capture different sources of perceived social support available, but not the depth and nature of that support. Future research could consider the use of a more detailed measure of perceived social support to capture the nature of the perceived social support, for example the child and adolescent social support scale (Malecki & Demaray, 2002).

The current study also relies on cross-sectional data, therefore limiting our ability to infer causal relationships between experiences of being bullied, perceived social support, and mental health difficulties. As discussed, further research is required to examine longitudinal relationships between being bullied, perceived social support and mental health difficulties. Such research would enable us to examine any possible bidirectional relationships between being bullied and perceived social support, for example whether those with a reduced level of perceived social support are more at risk of being bullied, or how the continuation of being bullied may result in a reduction in the perception of available social support.

Implications for practice

The findings of this study have important implications for professionals working with adolescents in school. When designing intervention and preventative programmes, the findings of the current study highlight the importance of capturing both bullying and cyberbullying in anti-bullying activities. The current study also highlights gender differences in the perception of social support and in the association between perceived social support and mental health difficulties in early adolescence. Our results highlight that perceived social support from friends and peers may not always be beneficial for girls. Encouraging those being bullied to seek help and enact upon available social forms the basis of a number of anti-bullying initiatives (Demaray & Malecki, 2006). Future interventions could also consider working with the school community to raise awareness of how best to support those being bullied.

Conclusion

The results highlight different associations between bullying, and cyberbullying, and mental health difficulties. These different relationships highlight the importance of studying both behaviors, rather than each in isolation. In addition,

the gender differences in the perception of perceived social support, and the

association with mental health difficulties, contribute to a complex body of literature

on the relationship between bullying, perceived social support and mental health

difficulties. Such gender differences may have implications for the effectiveness of

any interventions based around social support. Consistent with some previous

research, this study highlights that perceived support from friends and peers may not

always be protective, particularly for girls. Therefore, further research examining the

longitudinal relationship between experiences of being bullied, peer-relationships and

perceived social support is required to better inform intervention work.

Figure 1: Example Model
Note:
The multi-groups method was also used to test whether gender moderated the relationships presented in this model.

Table 1:
Descriptive statistics and correlations for bullying, cyberbullying and mental health difficulties

	1.	2.	M(SD)	
1.Bullying	-	-	1.60	(.79)
2.Cyberbullying	.60***	-	1.18	(.50)
3. Mental health difficulties	.39***	30***	1.74	(.54)

Notes: ***p<.001

Table 2:
Descriptive statistics and correlations shown by gender

	1.	2.	3.	Boys	Girls	t
				M(SD)	M(SD)	
1.Bullying	-	.55***	.35***	1.59 (.79)	1.61 (.78)	0.47, p=0.64
2.Cyberbullying	.65***	-	.23***	1.14 (.46)	1.22 (.53)	4.15***, d=0.16
3. Mental health difficulties	.45***	.35***	-	1.63 (.49)	1.84 (.58)	11.30***, d=0.20

Notes: ***p<.001, correlations for boys are shown above the diagonal, and for girls below.

Table 3:
The number (and percentage) of participants reporting who they would talk to if they were worried or concerned about something.

	Total		Boys		Girls		$\chi^2(1)$	φ
No-One	435	(11.6%)	295	(18.6%)	137	(7.6%)	65.90***	.10
Support from Family	2,338	(62.6%)	1,134	(60.5%)	1,197	(66.2%)	7.92**	.05
Support from Friends/ Peers	1,752	(46.9%)	663	(35.4%)	1,084	(60.0%)	232.20***	.20
Professional Support	766	(20.5%)	398	(21.2%)	363	(20.1%)	1.87	N/A

Notes: ** $p<.01$, ***$p<.001$

Table 4: *Moderation Analyses: the relationships between bullying, cyberbullying, perceived social support, and mental health difficulties*

	Males						Females					
	R^2	Unstandardized		Standardized			R^2	Unstandardized		Standardized		
		b	SEb	β	SE	95% CI		b	SEb	β	SE	95% CI	Z
Model 1: No social support	.12						.25						
Bullying		.22*	.03	.34*	.04	.26:.41		.30*	.04	.42*	.05	.33:.52	1.60

Notes:*p<.05

The z scores reported in the table represent gender differences in the unstandardized betas

Model 1: No perceived social support is coded as 1 = having no one to talk to, and 0 = having someone to talk to.

Models 2-4:1 = has support in that domain, and 0 = does not have support in that domain.

Higher mental health scores represent more mental health difficulties, lower scores represent better mental health.
