#### ABSTRACT

The use of analogues of previous river styles is highly significant for successful river restoration, yet some existing techniques available to assist practitioners are still not widely applied. We explore the use of Ground Penetrating Radar (GPR), to explore past river styles in an upland river valley in the UK, and explore the potential of the approach to reconstruct former channel pattern. Post-glacial evolution of upland floodplains has been influenced by temporal changes in vegetation, sediment supply and hydrological regime. Channelfloodplain morphodynamics over the Holocene were conditioned by glacial deposits, lateral interaction with slope processes and fluvial sediment reworking, changes in flow and sediment supply regimes driven by climatic change, and more recently direct and indirect anthropogenic activities, e.g. deforestation, floodplain land use and channel modification. Current drives towards river restoration often use floodplain topography as a guide to appraise such a planform state, however, reconstruction of former channel state is often restricted to surface features visible on historic maps and aerial photographs. This research focuses upon the floodplain of the upper Swindale Beck, Lake District, UK, which was recently restored to a planform design based on the recent meander pattern visible in floodplain topography. We show the potential of GPR to reconstruct a wider array of past channel pattern and evolution at a site characterised by largely aggradational conditions and consistent sediment supply from glacial deposits at the valley head. Analysis of GPR data from 40 intersecting GPR survey lines revealed several stratigraphic units, including gravel braidplains, berms, chutes and bars, several levels of larger channels and their layered fill as well as backwater deposits. These were interpreted as braided systems, dynamic wandering planform and single-thread meandering systems with spatial transitions conditioned by tributaries and valley slope. Optically Stimulated Luminescence (OSL) dates in combination with GIS analysis of valley slope, channel gradient and local valley floor aspect allowed the interpretation of individual evolutionary stages of river and floodplain development at Swindale over at least the last millennium and provides links to processes in the wider environment including the role of alluvial fans in supplying sediment and forcing channel migration. Such information can be particularly valuable for restoration projects to aid design of channel dimensions, planform configuration, channel gradient, substrate characteristics and connection with tributaries. While restoration generally aims to resemble a more natural reference state, specific targets may seek to improve a particular set of functionalities (e.g., ecological, flood and sediment management, recreational) which should be resilient to the consequences of ongoing climatic changes and should be achieved sustainably (e.g. locally sourced gravel). Here, GPR-based floodplain analysis provides a non-invasive approach to understand possible evolutionary trajectories and to appraise a wider range of restoration options and sustainable resources.

#### **1. Introduction**

River restoration design and construction predominantly focuses upon considerations of planform pattern and channel three-dimensional shape. Initial efforts at river manipulation for aesthetic and recreational purposes has been conducted for over a century ([Wohl](#page-19-0) et al., 2015; Podolak and [Kondolf,](#page-19-0) 2016), with creation of single-thread channels with riparian woodland [\(Kondolf,](#page-18-0) 2006) and introduction of instream structures to improve trout fishing e.g., in the US (Van [Cleef,](#page-19-0) 1885; [Hubbs](#page-18-0) et al., 1932; [Thompson](#page-19-0) and Stull, 2002). During the 1980s river restoration primarily concentrated on fish habitat improvements (e.g., Gowan and [Fausch,](#page-18-0) 1996), which involved introduction of plants, dead wood or morphological modification [\(Wohl](#page-19-0) et al., 2015). There has been an intensification in river re-naturalisation and restoration over the last three decades, in an attempt to restore physical and ecological functioning. In Europe, this in part has been driven by European legislation (EU Water and Habitats directives), and more recently in the UK through Natural Flood Management. During this period there has been an increasing realisation that successful restoration needs to be informed through geomorphological, hydrological and ecological concepts, requiring an interdisciplinary and catchment-scale approach [\(Harper](#page-18-0) et al., [1999;](#page-18-0) Sear, [1994](#page-19-0)). River restoration is a form of management that seeks to improve hydrologic, geomorphic and ecological processes ([Wohl](#page-19-0) et al., 2005), however, often the design includes additional functionality and targets such as natural flood management, sediment management, habitat quality, ecological diversity or recreational and aesthetic considerations [\(Wohl](#page-19-0) et al., 2015). It is increasingly thought that restoring full functionality to river systems is a way forward, using both hydrological and geomorphological knowledge and principles, to improve channel dynamism through reinstating former channel form (e. g., [Newson](#page-19-0) and Large, 2006; Sear, [1994;](#page-19-0) Soar et al., [1998;](#page-19-0) [Walker](#page-19-0) et al., [2007\)](#page-19-0). This often allows other targets to be met, such as improving floodplain connectivity, hydraulic diversity, water quality and sediment transport, thus often leading to improved habitat condition.

Although the problems within fluvial systems are often catchmentwide, river restoration has tended to focus on ad-hoc reach-scale efforts, often addressing the most severely degraded sections of river e.g., channelised areas [\(Harper](#page-18-0) et al., 1999). Current river restoration projects are wide-ranging, and may involve channel redesign ([Prior,](#page-19-0) 2016), usually informed by past channel styles, including restoration to a meandering planform [\(Kondolf,](#page-18-0) 2006), anabranching ([Medel](#page-18-0) et al., [2022\)](#page-18-0), or braided channels ([Brousse](#page-17-0) et al., 2021). Other projects have included reconnection of the channel with the floodplain recreating wetlands [\(Tockner](#page-19-0) et al., 1999; [Gumiero](#page-18-0) et al., 2013), replanting forest in upland areas (to increase interception and evapotranspiration) and on floodplains to increase hydraulic roughness ([Harper](#page-18-0) et al., 1999; [Anto](#page-17-0)[narakis](#page-17-0) and Milan, 2020), introducing large wood to rivers systems ([Grabowski](#page-18-0) et al., 2019), re-introducing beavers (Curran and [Cannatelli,](#page-18-0) [2014\)](#page-18-0), removing dams and weirs to improve longitudinal connectivity ([Sneddon](#page-19-0) et al., 2017; Garcia de [Leaniz,](#page-18-0) 2008), gravel augmentation ([Milan](#page-18-0) et al., 2000; [Arnaud](#page-17-0) et al., 2017), blocking artificial drainage systems e.g. upland grips ([Ramchunder](#page-19-0) et al., 2012), consideration of hyporheic function (Hester and [Gooseff,](#page-18-0) 2011), and more recently 'stage zero' approaches [\(Powers](#page-19-0) et al., 2019). All of these are informed to varying degrees by geomorphological, hydrological and ecological understanding and concepts.

Reach-scale channel restoration is often focused upon diversifying hydraulic habitat, and reintroducing such features as pool-riffle morphology, barforms and spawning gravels for fish, and reconnecting the channel to the floodplain. Usually there is an attempt to recreate the channel morphology prior to the channel being engineered. Often the challenge to the river restoration practitioner is defining a reference state, and the channel morphology that should be restored ([Newson](#page-19-0) and [Large,](#page-19-0) 2006). The solution is not aways straightforward. Many early river restoration designs arguably were strongly steered towards the public perception view of what an ideal river should look like; usually single-thread meandering (e.g. [Prior,](#page-19-0) 2016), which for the UK at least we now know this not necessarily to be the case ([Lewin,](#page-18-0) 2010). However, river morphodynamics and planform configuration respond to changes in climate and land use and as such sustainable river management needs to incorporate planning for anticipated future changes [\(Church](#page-18-0) and [Ferguson,](#page-18-0) 2015). Intense precipitation has increased globally in the 20th century and is predicted to become more frequent in future, across many places ([Groisman](#page-18-0) et al., 2005; [Beniston,](#page-17-0) 2009). In the UK there is some evidence for increased flood magnitudes that may be associated with this climate change [\(Wilby](#page-19-0) et al., 2008; [Hannaford](#page-18-0) and Buys, 2012; [Dadson](#page-18-0) et al., 2017). The consequences for river systems are not only frequent extreme floods and related sediment fluxes, but also the reduced potential of river reaches to recover (e.g., maintain their previous planform configuration) from such events (Milan and [Schwendel,](#page-18-0) [2021\)](#page-18-0).

A number of studies advocate the use of fluvial audit approaches (Sear et al., [1995;](#page-19-0) Sear et al., [2009](#page-19-0)) to guide the practitioner towards sustainable approaches to river restoration. This usually will include a historical assessment of former channel pattern using historic aerial images, maps and LiDAR data to reconstruct former channel pattern and planform morphology (e.g. Sear, [1994\)](#page-19-0). However, the use of analogues of past river styles tends to be underused or sometimes ignored, partly due to the target of the river restoration but also due to the limited information or technology available. Although there have been recent advances in the availability and application of remote sensing data for fluvial environments including its use in river restoration ([Entwistle](#page-18-0) et al., [2018](#page-18-0)), far less attention has been paid to the potential of subterranean information for river restoration.

Despite repeated calls for a more process-based approach to river restoration ([Beechie](#page-17-0) et al., 2010), it is relatively uncommon for an understanding of sub-surface sedimentology and stratigraphy to be used in river restoration but it has twofold potential. First, assessment of valley floor stratigraphy can give insight into past river and floodplain configuration, and associated evolutionary histories. However, simply attempting to create the previous channel morphologies, that functioned under a different hydrological and sediment supply regime, controlled by past climatic conditions and land-use, is not always a sustainable solution. Hence any re-designed channel must not only be based on contextual understanding of past channel form, but must also take into consideration contemporary and future trajectories in environmental forcing conditions. The utilisation of geophysical approaches coupled with dating methodologies have potential to address this gap and to shed light on the likely trajectory of past channel form development and suitability as a target for design (Sł[owik,](#page-19-0) 2015). Second, when processbased restoration is designed to give a river space to move ([Biron](#page-17-0) et al., [2014;](#page-17-0) Piégay et al., [2005\)](#page-19-0) and a river is expected to scour its bed and erode its banks [\(Williams](#page-19-0) et al., 2020) to adjust to variations in water and sediment discharge, understanding of sub-surface sedimentology can give insight into how vertical hydrologic connectivity may change ([Sparacino](#page-19-0) et al., 2019; [Howard](#page-18-0) et al., 2024) and the calibre of material that may be entrained and transported downstream. The primary methodological approach to map subsurface sedimentology is Ground Penetrating Radar (GPR). Its application in river restoration is uncommon but there are examples where surface GPR has been used to inform on past channel patterns as a basis for restoration (e.g. Sł[owik,](#page-19-0) 2015), identify boundaries in sediment stratigraphy ([Schneider](#page-19-0) et al., 2011), for the estimation of fine sediment depth and underlying coarse bedforms upstream of weirs using boat-based GPR ([Schwendel,](#page-19-0) 2019) and borehole and surface GPR for the characterisation of gravel aquifers ([Doetsch](#page-18-0) et al., [2010,](#page-18-0) 2012).

Here we argue that successful river restoration design can be informed by a full chronology of channel response over time. To achieve this, river restoration practitioners should have a variety of tools available at their disposal to make informed decisions. In this paper we explore the use of Ground Penetrating Radar (GPR) as an additional tool to the river restoration practitioner, to inform on historic channel <span id="page-3-0"></span>pattern and evolution. The specific aims of our investigation were:

- 1) Reconstruction of stages of channel planform development and floodplain evolution based on GPR data in the context of local conditioning influences (e. g. alluvial fans, moraines);
- 2) Appraisal of the temporal scale of such development;
- 3) Contextualisation of more recent anthropogenic alterations (straightening and realignment during restoration) with past river styles;
- 4) Evaluation of the benefits of GPR floodplain survey as a tool for river restoration practitioners.

#### **2. Study site**

#### *2.1. Site context*

The common channel morphology during the mid-Holocene in the UK was multi-thread anastomosed (Brown and [Keough,](#page-17-0) 1992). Human impacts upon UK rivers date back to the Bronze Age when human activity significantly altered this channel form and associated riparian forest, and with evidence of landscape-scale deforestation detectable in the pollen record [\(Brown,](#page-17-0) 1997; [Heritage](#page-18-0) et al., 2021). As farming practices improved through the Iron Age, tree felling became more widespread altering catchment-scale hydrology and sediment supply,

**Fig. 1.** Location of the study site a) within British Isles (data source: Natural Earth) and b) the English Lake District. The catchment at the downstream end of the study site is shaded in red (data sources: CEH, ESRI, Natural Earth). Panel c) shows a 2020 lidar DTM of the glacial trough valley of Swindale with the study site indicated by GPR profiles (Data source: National Lidar Programme, 2021, Open Government Licence). Valley confinement due to bedrock outcrops is visible downstream of the site. Glacial deposits, as mapped by the British Geological Survey (BGS, [2013](#page-17-0)) and in detail by [Bickerdike](#page-17-0) et al. (2016), and alluvial fans (AF) provide sediment and lateral constraint. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

<span id="page-4-0"></span>with subsequent effects on channel and floodplain form and function. Low intensity farming existed alongside unconstrained rivers until the Middle Ages, after which channel modification became more common and significant areas of wetland were drained to increase productivity. Anastomosed channels possibly in fossilised form are thought to have been the dominant channel type up to late Medieval period [\(Lewin,](#page-18-0) [2010\)](#page-18-0). Human impact accelerated after the 15th century, where rivers were impounded to provide water for agriculture and power ([Bravard](#page-17-0) and [Petts,](#page-17-0) 1996), and floodplains in the UK changed drastically [\(Lewin,](#page-18-0) [2013\)](#page-18-0). By the 1900s rivers in industrial Britain had been extensively channelised, restricting movement and natural morphological development ([Johnson,](#page-18-0) 1954). Modified straight channels often had levees along the bank tops, effectively disconnecting the channel from the floodplain. Over the 20th century, land drainage and flood relief saw further loss of natural river and floodplain form and function. More recently, post-World War 2 agricultural intensification saw artificial drainage systems installed in large areas of land in catchments, intensifying runoff of both water and sediment, and altering hydrograph shapes [\(Holden](#page-18-0) et al., 2006). Rapid urbanisation also influenced hydrograph character and sediment supply ([Miller](#page-18-0) and Hess, 2017). As floodplain productivity increased and land values rose, these areas were protected from flooding by embanking, decreasing channel-floodplain connectivity, and increasing flood risk downstream.

#### *2.2. Site description*

The study site at Swindale is situated at 265 m a.s.l. on the eastern edge of the English Lake District in a glacial trough valley with a tributary hanging valley (Mosedale) and a cirque-shaped valley head [\(Evans](#page-18-0) and Cox, [1995](#page-18-0); [Wilson](#page-19-0) and Clark, 1998) approximately 800 m upstream ([Fig.](#page-3-0) 1). Swindale Beck drains in a north-westerly direction to the River Lowther. The catchment upstream of the study site comprises  $15.3 \text{ km}^2$ of acidic grasslands with heather and bracken in the uplands and improved grassland with patches of woodland in the valley. Late Ordovician volcanoclastic sandstones and breccia of the Borrowdale Volcanic Group are overlain by till, peat and alluvial deposits [\(Millward,](#page-18-0) [2003\)](#page-18-0). Andesitic sills are cropping out in the channel downstream of the site (BGS, [2013\)](#page-17-0) where a water intake is located, and provide a local base level, thus creating a largely aggradational setting at the site. The same sills appear as a roche moutonneé near the valley head ([Wilson](#page-19-0) and [Clark,](#page-19-0) 1998), where Swindale Beck, coming from the hanging valley of Mosedale, erodes into a cluster of Younger Dryas moraines ([Lunn,](#page-18-0) 1990; [Wilson](#page-19-0) and Clark, 1998; [Bickerdike](#page-17-0) et al., 2016) (Fig. 2). [McDougall](#page-18-0) [\(2013\)](#page-18-0) suggests the possibility that glaciation extending from summit icefields could have extended further down-valley across the study site during this stadial and indicates associated moraines ([Fig.](#page-3-0) 1c). Other

geomorphological features in the valley include talus cones and alluvial fans associated with high gradient tributaries (BGS, [2013](#page-17-0)) (Fig. 2).

At the study site the channel had been straightened prior to the first edition of the Ordnance Survey map for this area (surveyed 1858 to 1859, published 1863) for improved agricultural use of the floodplain with the latter also being drained. The banks of the straightened channel were protected by a boulder toe in places (Reid, [2015\)](#page-19-0). The substrate was dominated by cobbles with some gravel with median grain size ranging from 82 mm upstream to 133 mm downstream ([Reid,](#page-19-0) 2015). In 2016 a United Utilities and RSPB led two-phase restoration scheme was implemented that aimed to improve river habitat quality and wildlife recovery while maintaining farm operations (hay meadows) on the floodplain ([Wightman](#page-19-0) and Schofield, 2021). The design of Phase 1 was guided by palaeochannel mapping, channel coring to determine the existence and elevation of gravel deposits, interpretation of floodplain elevations to determine flowpaths across the floodplain, and involved designing channels using hydraulic geometry principles. The Phase 1 restoration realigned a previously straight, incised channel to a meandering planform, guided by the sinuosity observed in well-defined palaeochannels on the floodplain in the downstream segment of the study site. Phase 2 involved remeandering the upstream segment of the scheme. Compared to Phase 1, the scheme design had a lower sinuosity. The phases were joined where the Beck was previously straight. The former straight channel was in most places backfilled with spoil from excavation of the new channel [\(Fig.](#page-5-0) 3). The scheme is part of a broader set of nature-based catchment management approaches that have been implemented throughout the catchment ([Hankin](#page-18-0) et al., 2019). The floodplain is largely flat with some partially infilled channels of lower width than the current single-thread channel. It was used at the time of investigation as a hay meadow. The study site forms part of the Site of Special Scientific Interest (SSSI) Swindale Meadows and is designated a Special Area for Conservation.

#### **3. Methods**

#### *3.1. Ground Penetrating Radar and coring*

At Swindale the floodplain stratigraphy was explored in July 2018 with Ground Penetrating Radar (GPR) at 40 intersecting survey lines ([Fig.](#page-5-0) 3) with a total length of 3283 m, covering an area of approximately 5.1 ha. The grassland had been recently mown apart from deep depressions which were not surveyed across. A PulseEkko Pro GPR (Sensors&Software, Mississauga, Canada) with a 100 MHz antenna and constant separation of 1 m from the receiver was used in reflection mode (time window 200 ns, step size: 0.25 m, 250 samples per trace and a stack height of 32). These settings are suitable for investigations in

**Fig. 2.** Geology of Swindale (Data source: DiGMapGB-10, 1:10000 using EDINA Geology Digimap Service). The studied area is indicated by GPR profiles. Andesite outcrops in the valley downstream of the study site (shown by the location of GPR profiles) provide base level control for floodplain evolution.

<span id="page-5-0"></span>

**Fig. 3.** Detailed location of GPR profiles, OSL samples and cores in Swindale. The survey was carried out in 6 areas (A to F) separated by the current channel of Swindale Beck, dry stone walls or deep palaeochannels that could not be traversed by the GPR cart. The river channel has been realigned in 2016 but the course of the former straight channel can still be seen as a faint pattern in the grass east of areas E and F and traversing areas C and B (see also facies VI in [Fig.](#page-8-0) 5d). High resolution (25 cm) vertical aerial imagery from 2018 has been sourced from Getmapping using EDINA Aerial Digimap Service.

floodplains with potentially conductive soil [\(Vandenberghe](#page-19-0) and van [Overmeeren,](#page-19-0) 1999; Słowik, [2012b\)](#page-19-0) and have been successfully applied in similar settings (e.g. [Bridge](#page-17-0) et al., 1995; [Gourry](#page-18-0) et al., 2003; [Kostic](#page-18-0) and [Aigner,](#page-18-0) 2007; [Hickin](#page-18-0) et al., 2009; Dara et al., [2019](#page-18-0); Sł[owik](#page-19-0) et al., [2021;](#page-19-0) Elznicová et al., 2023). Signal velocity was assessed from diffraction hyperbolas at several profiles and depths. As the identified velocities were similar across profiles and depths a mean value of 0.075 m/ns was subsequently adopted for all profiles for consistency. This allows a nominal vertical resolution (separation between two reflectors) of approximately 0.19 m ([Neal,](#page-19-0) 2004). Depth penetration of the radar signal was limited by material of high electric conductivity at a depth of 1.5–4 m which is most likely associated with glacial deposits.

The start, end and some intermediate points of each profile were recorded in the field with a Leica 1200 dGNSS system (Leica Geosystems, Heersbrugg, Switzerland). Surface topography was measured in a GIS (ArcMap 10.5.1, ESRI, Redlands, USA) from a publicly available 1 m aerial lidar DTM from 2021 (Environment Agency, UK).

GPR data processing was carried out in ReflexW 9.1 (Sandmeier, Karlsruhe, Germany) and involved Devow, background subtraction, application of an exponential gain function and topographic correction ([Neal,](#page-19-0) 2004). Further processing such as bandpass filtering or dynamic correction did not result in improved radargrams and was therefore not used. Some profiles benefitted from the application of the calculation of instantaneous amplitudes (envelope filter) in order to simplify reflections and to show their true resolution.

After preliminary analysis, 19 locations for ground truthing (Fig. 3) were selected and cored up to a maximal depth of 2.1 m using an Eijkelkamp hand auger. The depth of coring was limited by the presence of coarse layers that were either impenetrable or caused collapse of the bore hole. Additional information was derived from cutbank exposures of the new river channel, OSL pits, information obtained during the restoration works and earlier explorative pits (Lee Schofield, RSPB, personal communication 7/08/2019).

Electromagnetic radar waves are reflected on subsurface discontinuities characterised by variations in dielectric permittivity, electrical conductivity and magnetic permeability. These material properties allow conclusions on water and ion content, porosity, grain size assemblage, and grain packing and orientation ([Neal,](#page-19-0) 2004; [Cassidy,](#page-17-0) [2008\)](#page-17-0). Thus, the radargrams and core data allowed identification of several facies types and surfaces at a range of scales corresponding to sedimentary and morphological units which were mapped in GIS. The spatial distribution of these facies, their absolute elevation and their depth relative to the current floodplain surface were used to reconstruct planform styles and stages of floodplain evolution. Projected gradient of channels and surfaces, their aspect as well as their geometry and dimensions were employed to infer flow directions and continuity. The

latter was challenging due to the spacing between GPR lines relative to the dimensions of the identified units and the gaps in the survey associated with the current channel.

#### *3.2. Optically stimulated luminescence (OSL) dating and dose rate determination*

A total of six samples for optically stimulated luminescence (OSL) dating were collected in March 2023 from fine-grained (silt and sand) alluvial units and sandy interbeds within coarser-grained units exposed in two pits excavated into the floodplain and a NW-facing cutbank at the toe of an alluvial fan (Fig. 3). The locations were chosen after analysis of the GPR data to provide age constraint for radar facies II and III as well as lateral fan activity. Sampling was carried out at several depths in pits 1 and 2 in alignment with the encountered stratigraphy whereby sampling of the coarsest units was limited by the aperture size of the tubes. Following the approach of Pope et al. [\(2008\)](#page-19-0), sections were cleaned back with a trowel prior to light-tight stainless-steel tubes (3 cm in diameter and 20 cm in length) being gently tapped horizontally into targeted finegrained units. Once filled with sediment, the tube was capped on the outer side to prevent accidental light exposure before being carefully extracted, followed by plugging also its inner end with a plastic cap and sealing with duct tape. Each tube was then given a unique identification code and placed in airtight sample bags to preserve field moisture content. Following the extraction of each tube, a background sample  $({\sim}300 \text{ g})$  of sediment representative of a 50 cm three-dimensional sphere was collected directly around the sampling point for dose rate determination. Finally, key sample details including longitude, latitude, altitude and burial depth from the top of the section and unique identification code were recorded.

All luminescence samples were processed at the Nordic Laboratory for Luminescence dating (Risø, Denmark), following the methodology outlined by [Murray](#page-19-0) et al. (2021). Environmental dose rate measurements were performed using high resolution gamma spectrometry ([Murray](#page-18-0) et al., 1987, 2018), on sub-samples cast into a fixed geometry. Radionuclide concentrations can be found summarised in Table S1. OSL measurements were performed in a Risø OSL Reader (Bø[tter-Jensen](#page-17-0) et al., [2010](#page-17-0)), on coarse grains, using a standard SAR protocol for quartz ([Murray](#page-18-0) and Wintle, 2000, 2003) as illustrated by Table S2, and a post-IR IRSL SAR protocol [\(Thiel](#page-19-0) et al., 2011) for k-feldspar as shown in Table S3. The D<sub>e</sub> estimates and ages obtained from the k-feldspar are presented in Table S4, while those for quartz can be found in Section 3.2 ([Table](#page-6-0) 1). The full details of the analysis are outlined in the supplementary information file.

#### <span id="page-6-0"></span>**Table 1**

#### *3.3. Planimetric channel change*

A sequence of Uncrewed Aerial Vehicle (UAV) flights were undertaken before restoration, in 2015, and after restoration in 2016, 2017, 2018, 2020 and 2023 to acquire sets of oblique, overlapping Red Green Blue (RGB) images at low flow. A variety of DJI UAV platforms were used, including a Phantom 2 Vision ([Williams](#page-19-0) et al., 2017), Phantom 4, Phantom 4 RTK and an L1 sensor mounted on a Matrice 300 ([MacDonell](#page-18-0) et al., [2023\)](#page-18-0). For each survey, a set of targets were distributed across the site and observed using Real Time Kinematic Global Navigation Satellite System (RTK-GNSS) survey. The images were processed using structurefrom-motion photogrammetry [\(Smith](#page-19-0) et al., 2015), using Pix4D software. For each survey, the three-dimensional root mean square error at check point targets was *<*0.1 m. The extent of the wet channel was digitised from the orthomosaic that was produced from each survey.

#### **4. Results and interpretation**

#### *4.1. GPR facies*

Analysis of the radargrams revealed several facies across the study area, many of which could be identified in core logs. These were then classified into 10 classes based on their spatial relation and dimensions ([Fig.](#page-7-0) 4). While some cores terminated in wet fills of former channels, none reached the groundwater table and thus all surfaces are interpreted as dominantly changes in stratigraphy.

#### *4.1.1. Facies I* – *till*

This radar facies is laterally continuous with an undulating upper surface ([Fig.](#page-7-0) 4). The latter can be indistinct but is often indicated by diffraction hyperbolae near the upper boundary which may represent glacial cobbles and boulders. This facies can contain point reflectors at greater depth but is otherwise relatively unstructured and signal attenuation is high. It can be found at depth across the entire floodplain, although in the upstream area F its upper boundary can be up to only one metre below the surface [\(Fig.](#page-8-0) 5).

Słowik [\(2011\)](#page-19-0) suggests such zones of dense diffraction hyberbolae align with changes in lithology within glacial deposits while others have associated them with glacial boulders and cobbles within till ([Bridge](#page-17-0) et al., [1995](#page-17-0); Pedersen and [Clemmensen,](#page-19-0) 2005) where the clay matrix can result in high signal attenuation ( $\acute{E}$ kes and [Hickin,](#page-18-0) 2001). Thus, radar facies I has been interpreted as till of the Dimlington or Loch Lomond Stadials, consisting of silty clay with gravel to boulders [\(Millward,](#page-18-0) [2003\)](#page-18-0). While this facies has not been cored, it has been encountered at depth during the restoration works (George Heritage, personal communication 26/06/2019).

#### *4.1.2. Facies II* – *braidplain*

This is a laterally continuous radar facies consisting of subparallel reflectors with a wavy appearance and some crossbedding ([Fig.](#page-7-0) 4). In places it includes discontinuous concave reflectors and sub parallel dipping reflections. The facies' upper boundary is undulating and concordant, and appears to be notably lower (e.g. in places *>*1 m) below the present floodplain surface in area C compared to the rest of the site ([Fig.](#page-8-0) 6). Its vertical extent typically varies between 2 and 3.5 m with a distinct increase in upvalley direction in area E [\(Fig.](#page-9-0) 7). Apart from the western part of the upvalley area F, it is present throughout the study site [\(Figs.](#page-8-0) 5 and 8a).

Radar facies II has been interpreted as an aggrading braidplain with medium-sized channels, lateral accretion and channel fills over several storeys. In area D channels are larger (e.g., *>* 5 m) which might indicate a transition to a wandering planform. Based on depth correlation this facies has been just reached in cores such as 1 or 7 which suggest composition of sandy subrounded gravel [\(Fig.](#page-11-0) 9). Very similar radar facies collected by other studies on floodplains have been confirmed as being associated with braidplains [\(Vandenberghe](#page-19-0) and van Overmeeren, [1999;](#page-19-0) [Baines](#page-17-0) et al., 2002; Słowik, [2012a\)](#page-19-0).

#### *4.1.3. Facies III* – *wandering planform deposits*

This facies is characterised by a laterally moderately continuous (from several metres to tens of metres), strong reflector which forms the mostly concordant upper boundary ([Fig.](#page-7-0) 4). It can be subdivided into two sub-facies, a) radar facies IIIa which is largely planar or lightly undulating and b) the more undulating radar facies IIIb. Facies IIIa is 0.5–1.25 m thick and is laterally terminated by downlap or onlap on other type III facies. Vertical stacking of thisfacies happens occasionally, e.g. at profile E18 [\(Fig.](#page-9-0) 7). Facies IIIb typically has a thickness of less than one metre and is laterally consistent with other type III facies while the lower boundary commonly baselaps onto radar facies II. Both subgroups of radar facies III are widespread across the entire study site with their deepest occurrence in area C as well as in association with deep palaeochannels in area D and C ([Figs.](#page-8-0) 5, 6 and 8a).

These facies have been reached by numerous cores which indicate a mixture of gravel of various calibre with sand and small cobbles for facies IIIa (cores 1, 5,  $Fig. 9$  $Fig. 9$ ) while facies IIIb is dominated by coarse sand and fine to medium, subrounded gravel, in places well sorted and layered (cores 3, 7, 9, 10). Comparable radar signals have been interpreted as bedload sheets (IIIa) or low-angle downstream accretion deposits (IIIb) in wandering rivers [\(Wooldridge](#page-19-0) and Hickin, 2005). [Bridge](#page-17-0) et al. [\(1995\)](#page-17-0) found similar facies to our facies IIIb and associated them with lateral accretion of point bars. These facies resemble the morphology and grain size characteristics of contemporary wandering single-or multithreaded rivers (e.g. [Wooldridge](#page-19-0) and Hickin, 2005;

<span id="page-7-0"></span>

**Fig. 4.** Radar facies identified at the Swindale Beck floodplain. Solid lines are associated with the facies in question while dotted lines show neighbouring or internal reflections.

[Schwendel](#page-19-0) et al., 2010). Hereby radar facies IIIa represents flat-topped gravel berms with down valley propagation of individual units while radar facies IIIb represents associated small-sized chute channels and bar deposits.

#### *4.1.4. Facies IV* – *bar margin lateral accretion deposits*

This radar facies consists of multiple oblique parallel reflectors which dip at low angles (10◦-20◦), often towards concave reflectors in radar facies II (Fig. 4). It has been interpreted as a series of lateral accretion sediments on bar edges, e.g. a point bar in profile E17 [\(Fig.](#page-9-0) 7), associated with medium-sized channels particularly common in areas C,

D and E [\(Figs.](#page-8-0) 5, 6 and 8b).

Such radar facies have been found to form accretion surfaces of compound bars in braided systems (Lunt et al., [2004;](#page-18-0) [Hickin](#page-18-0) et al., 2009; Słowik, [2012a](#page-19-0)) while Bridge et al. [\(1995\)](#page-17-0) identified similar dipping lowamplitude reflectors as lower point bar gravels and sands of a singlethread meander bend.

#### *4.1.5. Facies V* – *coarse splay/ compaction*

Radar facies V is characterised by a planar, horizontal lowamplitude, near-surface reflector with a concordant upper boundary (Fig. 4). The lower boundary is concordant or onlapping onto a variety

<span id="page-8-0"></span>

**Fig. 5.** Radargrams of profiles D14 (top) and F25 (bottom) with radar facies annotated in Roman numerals. Broken lines indicate less clear boundaries between facies or internal structures within a radar facies.

Broken lines indicate less clear boundaries between facies or internal structures within a radar facies. Where applicable the location of cores is shown with simplified indication of grainsize. For more details on the cores, see [Fig.](#page-11-0) 9.

of other facies. Lateral extent is limited although this facies may be in places disguised by the ground wave. It can be considered of small vertical extent (*<*0.5 m) and contains well rounded particles up to coarse gravel calibre as evident in cores 13 and 18 [\(Fig.](#page-11-0) 9). Facies V can be found in all areas of the study site ([Fig.](#page-10-0) 8c).

Based on the core data, two interpretations are possible. This facies

<span id="page-9-0"></span>

**Fig. 7.** Radargrams of profiles E17 (top) and E18 (bottom) with radar facies annotated in Roman numerals. Broken lines indicate less clear boundaries between facies or internal structures within a radar facies. Where applicable the location of OSL pits is shown with simplified indication of grainsize. For more details on the stratigraphy, see [Fig.](#page-12-0) 11.

can be interpreted as coarse, superficial flood splay deposits forming a coherent layer of gravel, perhaps thickening in topographic depressions as in profile B10 and core 13 [\(Figs.](#page-11-0) 9 and 10). On the other hand, profile B7 and core 18 show a much less coherent distribution of medium gravel clasts but the surface has been artificially compacted during artificial infilling of redundant channels (see facies VI below). Słowik [\(2014a\)](#page-19-0) identified horizontal and wavy reflectors as being associated with a "toughened cartroad" surface and associated construction works (Słowik, [2012a](#page-19-0)). While this documented radar signal bears some similarity to radar facies V, the coarse grain size of this layer makes it more distinguishable from the facies below which is not the case at Swindale.

#### *4.1.6. Facies VI* – *artificial channel fill*

This facies, apart from some ringing noise, is largely reflection free. Its upper boundary is concordant, often with radar facies V, while the planar lower boundary is identified by a high-amplitude, concordant, planar reflector [\(Figs.](#page-7-0) 4 and 10) although signal attenuation can be high. The facies has a distinct lateral boundary with various other facies suggesting an erosional contact. This facies is restricted to locations in areas B and C where the straight channel, infilled in during the restorations works, was situated [\(Fig.](#page-10-0) 8d).

Given this information interpretation as artificial channel fill comprising fine material intermixed with organic matter, gravel and individual cobbles is straightforward. The lack of internal structure and strong attenuation is typical for highly conductive material (Ékes and [Hickin,](#page-18-0) 2001). Cores 18 and 22 ([Fig.](#page-11-0) 9) indicate a tendency of fining with depth until the coarse, armoured former channel bed is reached at depths of 1.1 m and 1.25 m respectively.

#### *4.1.7. Facies VII* – *channel fill*

Radar facies VII consists of planar to lightly undulating or dipping, weak parallel reflectors with an onlapping lower boundary [\(Fig.](#page-7-0) 4). The facies is laterally constrained by high-amplitude, concave reflectors (typically facies X, e.g. [Figs.](#page-8-0) 5, 6 and 10). It can be found across the

entire study site but is most common in the down-valley areas A, B and C ([Fig.](#page-10-0) 8b). It has been reached by numerous cores which indicate that alternate layering of mostly moderately sorted coarse (e.g., fine gravel, coarse sand) and dark fine sediments (e.g., silt, fine sand) whereby the coarser fractions are mostly angular and the finer layers may contain substantial organic matter or show signs of hydromorphy such as mottling and nodules (cores 2, 6, 10, 17 in [Fig.](#page-11-0) 9). Core 8 revealed some weak laminations within the depth range of this radar facies.

This facies has been interpreted as fill of topographic depressions such as inactive channels with fine backwater deposits and episodically coarser bedload from floods but may also include some bar sediments near the channel edges. The presence of organic matter is typical in such a setting ([Bristow](#page-17-0) et al., 1999), likely contributing to anoxic conditions in stagnant waters. This interpretation coincides with that of other studies of very similar facies, e.g. Słowik [\(2012a\)](#page-19-0) and Dara et al. [\(2019\)](#page-18-0) interpreted them as channel fill sediments although in the latter they were lacking the distinct internal structure found here.

#### *4.1.8. Facies VIII* – *backwater deposits*

This facies is characterised by laterally extensive planar horizontal parallel reflectors of low amplitude ([Fig.](#page-7-0) 4). Its upper boundary is often not clear in the radargrams but cores indicate a clear boundary to mostly coarser sediments above at 0.15–0.25 m depth (e.g., cores 3, 4, 7, 11, [Fig.](#page-11-0) 9). At the respective depth these cores show grainsizes from silty clay to silt. The lower boundary of radar facies VIII onlaps onto other facies (e.g., type III) or is concordant with radar facies VII [\(Fig.](#page-8-0) 6). Thickness of this facies is greatest in area C where it is also most widespread while its vertical extent is less and more variable in the other areas [\(Fig.](#page-10-0) 8c).

The fine nature and horizontal stratigraphy suggest a low energy depositional environment without episodical coarse flood deposits such as backwaters or a temporary lake. The coarsening and thinning of this facies away from area C and the southern part of area A suggests approach of the margins of such a backwater basin. Similar radar facies

<span id="page-10-0"></span>

**Fig. 8.** Spatial distribution of radar facies across study site in Swindale. a) Depth of upper boundary of facies III and southwestern limit of the underlying facies II. Location of facies VII, IV and IX, and facies VIII and V are shown in b) and c) respectively. d) Depth of upper boundary of facies associated with channels (X and VI). Where facies are stacked only depths for the uppermost facies are given. Background DTM detrended for valley slope is based on data from the National Lidar Programme 2021 (Open Government Licence).

but with higher proportion of organic material were interpreted by Słowik [\(2013\)](#page-19-0) and Słowik [\(2014b\)](#page-19-0) as organic fill of stagnant water basins on the Obra River and as homogeneous fine palaeochannel fill by [Elznicov](#page-18-0)á et al. (2023).

#### *4.1.9. Facies IX* – *prograding channel deposits*

Radar facies IX consists of gently inclined oblique sigmoidal reflectors downlapping and onlapping onto other radar facies, e.g. facies X and facies III respectively ([Fig.](#page-7-0) 4). Spatially it is often associated with facies VII and X (Figs. 8 and 10). The facies has been reached by cores 2, 11, 17 and possibly 24, which all agree on grain sizes in the gravel range ([Fig.](#page-11-0) 9). Core 17 suggests some layered strata but dipping angle could not be measured.

Based on the radargrams this facies has been interpreted as prograding channel deposits possibly associated with lateral or downstream accretion or bar slipface deposition in the larger channels. Similar radar facies have been interpreted as pointbar migration [\(Vandenberghe](#page-19-0) and van [Overmeeren,](#page-19-0) 1999; Dara et al., [2019\)](#page-18-0), downstream bar accretion deposits ([Wooldridge](#page-19-0) and Hickin, 2005; Elznicová et al., 2023) or prograding splay deposits ([Bristow](#page-17-0) et al., 1999).

#### *4.1.10. Facies X* – *erosional surfaces*

Radar facies X is characterised by laterally discontinuous, concave high-amplitude reflectors ([Fig.](#page-7-0) 4). Symmetric, asymmetric, more semi-

<span id="page-11-0"></span>

**Fig. 9.** Stratigraphic profiles of 19 soil cores taken along radar profiles at Swindale in August 2019 (for the precise location see [Fig.](#page-5-0) 3). All cores are displayed with the same depth scale. Grainsize is shown on the horizontal axis as C – clay, U – silt, fS – fine sand, cS – coarse sand, fG – fine gravel and cG – coarse gravel. Where the dominant grain size is mixed with substantial amounts of other grain sizes this is indicated by coloured patterns (see legend).

**Fig. 10.** Radargrams of profiles B8 (top) and B10 (bottom) with radar facies annotated in Roman numerals. Broken lines indicate less clear boundaries between facies or internal structures within a radar facies. Where applicable the location of cores and OSL pits is shown with simplified indication of grainsize. For more details on the stratigraphy, see Figs. 9 and 11.

<span id="page-12-0"></span>circular or trapezoidal as well as compound forms have all been grouped into this facies, but it has been sub-divided into two sub-facies based on lateral extent: sub-facies Xa with *>*5 m and sub-facies Xb for smaller features. This radar facies is laterally mostly associated with facies II and III.

Sub-facies Xa is present in all areas but particularly frequent along profiles C34 [\(Fig.](#page-8-0) 6), B10 [\(Fig.](#page-11-0) 10), E17 and E18 ([Fig.](#page-9-0) 7) while sub-facies Xb is equally distributed across the site apart from area B [\(Fig.](#page-10-0) 8d). Areas B, C and D harbour the deepest examples of the facies while they are rather shallow below the contemporary floodplain surface in area F ([Fig.](#page-8-0) 5). Core data indicates that it consists of gravel deposits (cores 3, 10 and 11 in [Fig.](#page-11-0) 9). Geometry and grain size lead to the interpretation of this facies as erosional surfaces such as channel bottom and coarse bar deposits which corresponds with interpretation of similar radar facies by others (Ékes and [Hickin,](#page-18-0) 2001 (facies 8); Heinz and [Aigner,](#page-18-0) 2003; [Hickin](#page-18-0) et al., [2009;](#page-18-0) Słowik, [2012a;](#page-19-0) Dara et al., [2019](#page-18-0) (facies 5)).

#### *4.1.11. Vertical floodplain accretion*

Apart from the cores situated in artificial channel fill, all cores show vertical accretion sediments from the surface to a depth ranging from 0.05 m to 0.3 m [\(Fig.](#page-11-0) 9).

#### *4.2. Luminescence dating*

The measured OSL ages for the sample from the toe of the alluvial fan AF1 shows the oldest age with  $5.22 \pm 0.35$  ka ([Table](#page-6-0) 1). It comes from the fourth lowest distinctive layer within this profile (Fig. 11) and so may not represent the most recent date of fan activity at this point, however, the calibre of coarse clasts in the layers above prevented sampling for OSL. The ages of samples representing radar facies III (OSL1.2 and OSL2.3: ~1.7 ka) and the transition between facies II and III (OSL1.1 and OSL2.2:  $\sim$ 3.65 ka) correspond well between the two pits. However, given the discrepancy between feldspar and quartz ages as expressed in high IR50/OSL ratios ([Table](#page-6-0) 1) this is likely coincidental.

It has been well documented that partial bleaching of the luminescence signal prior to deposition can lead to significant age overestimation in some fluvial settings (Jain et al., [2004;](#page-18-0) [Wallinga,](#page-19-0) 2008; [Murray](#page-18-0) et al., 2012; [Weckwerth](#page-19-0) et al., 2013; [Colarossi](#page-18-0) et al., 2015; [Chamberlain](#page-17-0) and Wallinga, 2018). This problem results from the very rapid attenuation of light spectra through the water column, leaving insufficient energy to fully reset the luminescence signal [\(Berger,](#page-17-0) 1990); the addition of suspended sediment further enhances the effect ([Berger](#page-17-0) and [Luternauer,](#page-17-0) 1987). The potential for bleaching of sand sized grains

in fluvial settings is known to be further reduced by short transport distances as opportunities for light exposure are limited ([Cunningham](#page-18-0) et al., [2014](#page-18-0)). Bleaching would appear to be enhanced by longer transport distances, possibly due to the potential for numerous subaerial exposures during ephemeral storage episodes on the surface of river bars ([Stokes](#page-19-0) et al., 2001). However, this does not appear to be universal guarantee of sufficient signal resetting, as mixing with older or poorly reset material remobilised from localised terrace erosion during high discharge storm events is also more likely to have taken place over longer transport distances [\(Rittenour,](#page-19-0) 2008; [McGuire](#page-18-0) and Rhodes, [2015\)](#page-18-0).

With no absolute assurance of sufficient signal resetting in fluvial environments it is vitally important to not take luminescence ages obtained from fluvial sediments at face value. Of the variety of methods routinely used to assess the bleaching status of such samples we have opted to employ the unambiguous bleaching properties of the quartz and potassium feldspar signals to test the validity of the ages presented in this study.

It has been observed that the post-IR signals in feldspar bleach much more slowly and are therefore much more difficult to reset than the  $IR_{50}$ signal, and that the  $IR_{50}$  resets much more slowly than the OSL signal in quartz [\(Poolton](#page-19-0) et al., 2002; Jain and [Ankjærgaard,](#page-18-0) 2011; [Murray](#page-18-0) et al., [2012\)](#page-18-0). It is therefore possible to draw conclusions regarding the completeness of signal resetting at the time of deposition in the quartz by comparing it to the harder to bleach feldspar. This is an approach that has been successfully demonstrated by Möller and [Murray](#page-18-0) (2015), [Alexanderson](#page-17-0) et al. (2024) and [Thompson](#page-19-0) et al. (2024). The post-IR feldspar ages significantly overestimate the corresponding quartz OSL ages in all samples with the exception of OSL 2.3 [\(Table](#page-6-0) 1). Unfortunately, this sample yielded no usable feldspar, and it is not possible to make any further comment on the signal resetting in this case. A comparison of the  $IR_{50}/OSL$  ages for samples OSL 1.1 and OSL 1.2 (Pit 1) also shows a significant overestimation, and therefore we cannot comment conclusively on the degree of signal resetting in these samples. The two samples are however stratigraphically consistent with each other. In Pit 2 there appears to be a stratigraphic inversion in the quartz ages. Comparing the IR50/OSL ages for the samples that yielded K-rich feldspar, we see that in OSL 2.1 this ratio is 1.11; as this is within  $2\sigma$  of unity we can conclude that the OSL signal in this sample was sufficiently well reset prior to burial. For sample OSL 2.2 the  $IR_{50}/OSL$  age ratio is 1.45, indicating that the quartz signal might not be as well bleached in this instance, and we should trust the age of the deepest sample OSL 2.1 more ([Table](#page-6-0) 1, Fig. 11). In the case of sample OSL 4.1 the ratio is much

**Fig. 11.** Stratigraphic profiles of the three pits (1, 2 and 4) dug to extract OSL samples at Swindale in March 2023 (for the precise location see [Fig.](#page-5-0) 3). All profiles are displayed with the same depth scale. Grainsize is shown on the horizontal axis as  $C - \text{clay}$ ,  $U - \text{silt}$ ,  $fS - \text{fine}$  sand,  $cS - \text{coarse}$  sand,  $fG - \text{fine}$  gravel and  $cG - \text{coarse}$ gravel. Where the dominant grain size is mixed with substantial amounts of other grain sizes this is indicated by coloured patterns (see legend).

<span id="page-13-0"></span>closer to unity (1.08), and we can be confident that the OSL signal was fully reset.

#### **5. Floodplain development**

Based on the combination of core, radar data and chronometric data several stages of floodplain development can be reconstructed (Fig. 12). In the localised context of upper Swindale such development is conditioned by the outcrop of an andesitic sill downstream of the study site ([Fig.](#page-4-0) 2) which provides local base level control. This limits erosion within at least parts of the study site and has preserved stratigraphic evidence of floodplain evolution. Furthermore, moraines and alluvial fans in the valley are sources for sediment supply to the studied reach ([Fig.](#page-3-0) 1c).

Radar facies I forms the base of the floodplain across the entire study site and is very likely associated with till. The depth of its upper boundary increases down-valley to up to 5 m below the current floodplain surface. The age of this till is not known precisely, although

**Fig. 12.** Stages of sequential floodplain and channel development at Swindale based on radar analysis. A) Stage 2, a multi-thread or wandering planform with several channel systems stacked. Identified substages indicate depth below the contemporary floodplain with substage 2a being the lowest. These substages are not necessarily correlated between the different areas (labelled A-F). Alluvial fans (AF) are potential sources of sediment. B) Stage 3 characterised by northerly drainage across areas A and B, likely caused by blockage of a channel on the south-eastern valley side (indicated by green dotted lines) for example by activity of alluvial fan 1 (red arrow). Backwater deposits have been found in areas A, B and C but have likely extended further south-east. C) Stage 4, a single thread or low-order multi-thread planform with its main channel largely outside the surveyed areas. Erosion along the toe of AF1 has enabled a shift to a south-easterly drainage route in the lower study area. Many superficial channels on the associated floodplain are still detectable from aerial imagery, constituting tributary channels and remnants from earlier stages. D) Stage 5, an artificially straightened channel with floodplain drainage. High resolution (25 cm) vertical aerial imagery from 2009 has been sourced from Getmapping using EDINA Aerial Digimap Service. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

[McDougall](#page-18-0) (2013) suggests that during the Loch Lomond Stadial (12.9–11.7 cal. ka BP) glaciers extended as far as the study site as evidenced by moraines preserved to the east of area A [\(Fig.](#page-3-0) 1c).

#### *5.1. Stage 1*

After the Loch Lomond Stadial (12.9–11.7 cal. ka BP), the initial stage of floodplain development coincided with the partial incision and concomitant burial of glacial till (facies I) by an evolving braided fluvial system. This system occupied almost the entire study site (apart from the northern part of area F) (Fig, 8a) and is characterised by channel and bar sequences (facies II and IV). The chronology of sandy gravels that constitute the basal and stratigraphically lower units of facies II has yet to be fully resolved. Nevertheless, a single OSL age estimate (c.  $5.22 \pm$ 0.35 ka) from an alluvial fan (AF1) suggests that deposition of the basal and lower sandy gravel occurred before the middle Holocene. Assuming this is the case, the oldest sandy gravel units are potentially analogous to radiocarbon dated terraced gravels in Bowderdale, in the Howgill Fells which were emplaced before 6763–7005 cal. BP (6070  $\pm$  70 BP: SRR-318) ([Miller,](#page-18-0) 1991) and the Upper Langden, in the Bowland Fells where deposition occurred prior to 5316–5573 cal. BP (4680  $\pm$  80 BP: WIS-1614) ([Miller,](#page-18-0) 1991).

The delivery of coarse-grained sediment to the valley floor via steep tributary valleys culminated in the progradation of alluvial fans across the margins of the braidplain (profile F25, 63–71 m, [Fig.](#page-8-0) 5) during the mid-Holocene (c. 5.22  $\pm$  0.35 ka). This phase of fan progradation appears to have initiated the local development of a wandering planform in the lower area E and area D of the braidplain evidenced by deep (buried) larger, possibly more permanent channels with point bars and associated accretion structures (facies IV, [Fig.](#page-10-0) 8b). It is not known if the floodplain environment was characterised by sustained aggradation or spatially selective reworking during the post-middle Holocene to late Holocene period. Following the middle Holocene, aggradation varied significantly in regional catchments. At Colley Moor, Northumbria, a radiocarbon date from a silty sand unit inset within soliflucted till suggests that in Coe Burn, a phase of fine-grained alluvium took place after 4259–4584 cal. BP (3920  $\pm$  70 BP:BETA-28982) [\(Macklin](#page-18-0) et al., 1991). By comparison, there is no compelling evidence of mid-Holocene aggradation in catchments in the Howgill Fells, Bowland Fells, and the Southern Uplands ([Chiverrell](#page-17-0) et al., 2007 and references therein). The scale of human activity and land use-change within the study area during the late Holocene is not known. Nevertheless, palaeolimnological evidence indicates that woodland clearances across the Lakeland Fells were minor and localised until c. 5200 cal. BP [\(Pennington,](#page-19-0) 1991), whereas the late Bronze Age to early Iron age (2700–2800 cal. BP) and particularly the late Iron Age and Romano-British periods (2300–1500 cal. BP) witnessed a significant increase in the distribution and intensity of clearances ([Pennington,](#page-19-0) 1978; [Hodgkinson](#page-18-0) et al., 2000; [Chiverrell](#page-17-0) et al., [2004](#page-17-0)). It is possible that the combination of localised clearances and the shift to wetter conditions around 5.2 ka, 4.2 ka, 3.6 ka, and 2.8 ka ([Charman,](#page-17-0) 2010; [Roland](#page-19-0) et al., 2015) led to intermittent aggradation in the braidplain environment in the period between the post-middle Holocene and start of the late Holocene.

A single OSL age (0.99  $\pm$  0.19 ka) from the lower sandy gravel unit of Facies II and the presence of several storeys of braidchannels suggest that a significant aggradation occurred across the floodplain started approximately 1000 years BP. Assuming this is the case, the lower sandy gravel unit is potentially analogous to lower terraced gravels that were the emplacement in the lower Ribble catchment c.1000 cal. BP [\(Chiti,](#page-17-0) [2004\)](#page-17-0) and in Kirtle Water, Southern Uplands between 1000 and 750 cal. BP [\(Tipping,](#page-19-0) 1995). The scale of human activity and land use-change occurring within the study area during this period is not known. Nevertheless, palaeolimnological evidence and pollen data indicate that significant woodland clearances occurred across the Lake District ([Pennington,](#page-19-0) 1991, 1997; [Dumayne-Peaty](#page-18-0) and Barber, 1998), the Howgill Fells ([Cundill,](#page-18-0) 1976), and Rotten Bottom in the Southern

Uplands ([Tipping](#page-19-0) et al., 1999) in response to a growing rural economy that coincide with the Norse settlement period (1200–950 cal. BP) ([Winchester,](#page-19-0) 1987). With woodland clearance from upland areas around Swindale, the steep tributary systems are likely to have transferred coarse- and fine-grained sediment to the floodplain zone (cf. [Harvey,](#page-18-0) [2002\)](#page-18-0). Nevertheless, the sustained rates of floodplain aggradation almost certainly reflect the progressive reworking and remobilization of glacial, paraglacial, and fluvial sediment stored upstream coupled with the downstream base level control exerted by the andesitic sill downstream of the study site and sediment storage opportunities linked to valley-floor configuration at Swindale (cf. [Passmore](#page-19-0) and Macklin, 2000; [Chiverrell](#page-17-0) et al., 2007).

#### *5.2. Stage 2*

The second stage of floodplain evolution is characterised by a loworder multi-thread or single-thread wandering planform ([Fig.](#page-13-0) 12a). It is mainly associated with radar facies III, representing bedload sheets, bars and transient chute channels, as well as lateral accretion deposits (IV). In addition, channels of various size are preserved (X) together with prograding coarse bar migration sediments (IX) and fine channel fills (VII). A geochronology for this stage of floodplain development is lacking. Nevertheless, an OSL age of  $0.99 \pm 0.19$  ka generated for facies II places the formation of facies III and hence the second stage of floodplain development within a late Holocene timeframe.

The shift from stage 1 to stage 2 is distinct in the GPR data and in places associated with considerable coarsening of the sediment calibre, e.g. facilitated by deposition of coarse bedload sheets over finer bar top sediments ([Figs.](#page-8-0) 5, 6, 7 and 10). However, whether these bars have been created in a braiding or wandering environment is often not resolved and thus the transition between the two stages might have been much more gradual. Such a shift could be attributed to changes in sediment supply due to climatic alterations as well as anthropogenic land use change, albeit with some lag time ([Chiverrell,](#page-17-0) 2006; [Larsen](#page-18-0) et al., 2013). However, given the limited dating control, it is not known if changes in sediment supply occurred during the 9th century CE (c.1000 cal. BP) or the following centuries CE. The erosion of soils and sediment in several Lakeland catchments is evidenced by the increased delivery of finegrained sediment to several Lake systems c. 1000 cal. BP and 500 cal. BP [\(Chiverrell,](#page-17-0) 2006 and references therein; Shen et al., [2008](#page-19-0)*;* [Hatfield](#page-18-0) and [Maher,](#page-18-0) 2009). In other areas of the Lake District, significant gullying and erosion linked to the exploitation of hillslopes culminated in alluvial fan progradation in Blind Tarn Moss (Easedale) and Derwent catchment, Borrowdale after 895-725 cal. BP (860  $\pm$  40 BP: SUERC-6686) ([Chiverrell](#page-17-0) et al., 2007) and 621-515 cal. BP (534  $\pm$  45 BP: OXA-7751) (Wild et al., [2001\)](#page-19-0), respectively. By comparison, in the central Southern Uplands, erosion resulting from the exploitation of hillslopes led to fan aggradation in Dalveen Pass (Lowther Hills) and Nitties Burn after 485–520 cal. BP (466  $\pm$  25 BP: SUERC-4704) and 310–460 cal. BP  $(330 \pm 70$  BP: BETA-95478) [\(Chiverrell](#page-17-0) et al., 2007), respectively. The temporal variability in sedimentation between catchments is likely to reflect differing levels of landscape (in-)stability within catchments ([Chiverrell](#page-18-0) et al., 2008) coupled with variable preservation potential of stream deposits and alluvial fan gravels in valley floor environments (e. g. [Lewin](#page-18-0) et al., 2005). Within Swindale, the continued availability of (glacial, paraglacial, and fluvial) sediment in upstream storage zones together with coupled and localised reworking of floodplain and alluvial fan sediments offers a potential explanation for aggradation spanning the 9th and 15th centuries CE (1000–500 BP). Additionally, the valley configuration created a 'buffer' effect leading to significantly greater reach-scale storage and preservation of floodplain sediments (e.g. [Lewin](#page-18-0) et al., [2005\)](#page-18-0).

Multiple levels of channels of varying dimensions have been found across the entire study site which allows distinction of several storeys. These substages indicated in [Fig.](#page-13-0) 12a refer to the depth below the contemporary floodplain surface of identified channel systems within each area. Elevation and channel dimensions were used to attempt the matching of substages between neighbouring areas. However, spatial gaps in the survey prevent correlating these systems across the entire study site but they nevertheless indicate floodplain architectures and possible channel planforms. Changes in channel dimensions may be attributed to variation in sediment supply, e.g. the incision of a deep channel along the toe of the fan AF3 (stage 2a in [Fig.](#page-13-0) 12a), and thus the ratio between transport capacity and sediment supply of the system ([Harvey,](#page-18-0) 2002). Large channels at depth [\(Fig.](#page-10-0) 8d) have been recognised on both sides of the valley (areas D, C and B) implying a dynamic system that used the full width of the valley. Erosion in more recent stages and anthropogenic interventions such as the excavation of the straight channel and, more recently, the re-meandered channel have removed evidence of floodplain development in the central parts of the valley. However, it is remarkable that no traces of deep or large channels have been found along the valley axis, e.g. in the western part of area C (profiles C29–32) and the eastern part of area B (profiles B7–9, B11 and B12; e.g. [Fig.](#page-11-0) 10). The detrended DEM [\(Fig.](#page-10-0) 8) indicates a topographic high along this axis in areas B and C and radar facies III is consistently deepest below surface level along the edges of the valley (profiles C36, C34, B10 and D14 respectively; [Figs.](#page-8-0) 5, 6 and 10), hereby indicating a gradient away from the valley centre axis. While the contemporary topographic high in the valley centre may be associated with levees and overbank deposition along the former straight channel [\(Reid,](#page-19-0) 2015; [Wightman](#page-19-0) and Schofield, 2021), an explanation for such an arrangement at depth is less straightforward. Potentially differential till deposition at the margin of the Younger Dryas glaciation might have favoured drainage along the valley edges where lateral fans allowed. As a result, the main channels may have shifted at intervals between a train of channels on either the NW or SE edges of the valley downstream of the narrow point created by the alluvial fans AF2 and AF3 at the up-valley end of the study site [\(Fig.](#page-3-0) 1c). Only in area A, likely beyond the margin of Younger Dryas glaciation ([Fig.](#page-3-0) 1c), there is clear evidence of cross-valley drainage as well as potentially one substantial channel in area B (stage 2d in [Fig.](#page-13-0) 12a). The reconstruction of drainage in area A suggests roughly E and NE drainage direction for most of this stage with a distinct shift to a northward drainage for the uppermost channels. This might be the result of blockage of a main channel at the eastern valley edge, for example by activation of alluvial fan AF1 there. Such an episode could have led to rerouting of drainage and temporary impoundment there, which is supported by apparent fading and fragmentation of radar facies III at the down valley end of profiles C34 ([Fig.](#page-8-0) 6), C35 and C36 and leads to development stage 3 in the downstream part of the study site.

#### *5.3. Stage 3*

The third stage is characterised by backwater deposits (radar facies VIII) extending across much of areas C and A and several N-S aligned channels across area A some of which are still evident in the contemporary floodplain surface [\(Fig.](#page-13-0) 12b). Such a shift to a northerly direction of the drainage in the lower study area may be explained by biogeomorphic alterations (e.g. beaver dams) or the mentioned westward extension of the alluvial fan AF1 and the resulting blockage of the previous southeastern alluvial drainage route. While the age of deposition at the toe of AF1 (pit 4) is much older than the developments in stage 3, other parts of the fan may have been active at different times. The ensuing impoundment would have rerouted channels to the north and created the substantial downvalley thickening deposits associated with radar facies VIII. It is possible that gradual fill of the basin has led to avulsion further upstream and reoccupation/ scour of a large channel through area B (stage 2b in [Fig.](#page-13-0) 12a). Whether this episode was triggered by a general reactivation of fan AF1, bio-geomorphic agents or avulsions and drainage changes within is unclear.

Channel fills (radar facies VII) as part of channel migration and abandonment within a wandering river floodplain are present as well

during this stage, however, this facies varies from the backwater facies VIII in its smaller horizontal extent, lateral onlap on channel facies X and presence of alternating layers. In contrast, facies VIII is less structured, fine throughout (at least in area A) and often situated over channel fills ([Fig.](#page-8-0) 6).

#### *5.4. Stage 4*

After incision of a new south-eastern channel along the toe of AF1, it is likely that the main channel reversed to the SE valley side again ([Fig.](#page-13-0) 12c). The previous N-S aligned spill channels across area A of stage 3 were filled (radar facies VII) or drained the floodplain. More recently after the channel restoration works some of these channels have been reactivated, albeit with a reversed flow direction towards the newly excavated channel, which they meet at an obtuse angle ([Fig.](#page-10-0) 8).

The radargrams show only the margins of the stage 4 main channel system (e.g., profiles B9, A5, C33, E19 and F27) suggesting a spatially constraint, likely single-thread or low-order multithread channel system and associated floodplain development. The reconstructed large bend on the SW end of area F (radar facies X on profile F24, [Fig.](#page-10-0) 8d) shows erosional contact with adjacent facies and may be associated with this system. During this stage vertical accretion sediments have been deposited across the study site suggesting a reduction in coarse sediment supply and channel stabilisation. Some superficial coarse splay deposits laid down during floods are found across the entire site (radar facies V, [Fig.](#page-10-0) 8c).

[Fig.](#page-13-0) 12c also shows an array of superficial channels evident only from radargrams as well as those also visible from aerial photography. These are likely to have linked tributaries to the main channel prior to floodplain drainage.

#### *5.5. Stage 5*

The last stage that is evident from the GPR survey is the anthropogenic realignment of Swindale Beck [\(Fig.](#page-13-0) 12d) and the insertion of drainage pipes in the floodplain. The fill of the straightened channel during the restoration works 2016 can be clearly seen as radar facies VI ([Fig.](#page-10-0) 8d). Some sediments associated with radar facies V [\(Fig.](#page-10-0) 8c) may present compacted soil as a result of the use of heavy machinery.

#### *5.6. Stage 6*

[Fig.](#page-16-0) 13 shows the planform dynamics of the extent of the active channel, defined as the mosaic of the low flow wet channel and unvegetated bars, since the 2016 channel realignment. Bank erosion at the outer banks of meander bends has resulted in channel migration, with the highest rates along the more sinuous set of meanders along Phase 1 (downstream segment of the scheme). The 2023 survey shows one area of bifurcation, upstream of the point where the realigned channel crosses the pre-restoration channel. Here, the realigned channel bifurcated during a high-flow event and a knickpoint worked upstream from the pre-restoration channel, which had not been infilled along this reach of former channel. However, during low flows this new channel remains dry. Overall channel adjustment has been gradual and during the sevenyear post-realignment monitoring period.

#### **6. Implications for river management**

The analysis of floodplain stratigraphy using GPR has been shown to allow reconstruction of key stages of the evolution of river styles and floodplain formation at Swindale. River management, including the planning and design of river restoration projects can draw various benefits from such an approach. In this context, GPR provides a spatially extensive, time and cost-efficient appraisal of floodplain stratigraphy using a non-invasive approach [\(Szuch](#page-19-0) et al., 2006) suitable for sensitive habitats, like the 'Site of Special Scientific Interest' at Swindale.

<span id="page-16-0"></span>

**Fig. 13.** Planform change at Swindale Beck following restoration. Channel extent for each year is based on low-flow, wet channel extent from orthoimages produced using UAV acquired images that were processed using SfM photogrammetry. The polygons showing the extent of the active channel are each partly transparent; where they overlay a mix of colours from different years is shown.

Knowledge of stratigraphy provides opportunities to facilitate sustainable river management approaches in several ways. Firstly, it allows the identification of past river styles and their interpretation in relation to sediment sources and lateral constraints (e.g., alluvial fans). Sł[owik](#page-19-0) [\(2015\)](#page-19-0) showed how geophysical floodplain investigation along with analysis of historical maps and aerial imagery can lead to the design of sustainable restoration schemes. Knowing the sensitivity of a fluvial system to local influences and the ensuing effects on planform change in the past are important to be considered for designing a restored system that will fulfil the restoration objectives in a changing climate. Not all restoration schemes aim to emulate a past river style and channel configuration but are driven by specific objectives. At Swindale, the restoration design aimed to primarily increase biodiversity in the valley while preserving the protected hay meadows and associated grassland plant communities [\(Wightman](#page-19-0) and Schofield, 2021) and thus opted for a single-thread channel form with increased channel sinuosity, creation of point bars and pool-riffle morphology. A secondary objective was not to increase sediment flux downstream, due to drinking water abstraction from the Beck in the reach immediately downstream of the realignment scheme [\(Wightman](#page-19-0) and Schofield, 2021). The development of a secondary high-flow channel in 2022 (Fig. 13) shows that under current climate and sediment supply conditions a wandering planform could develop and that implementation of such a system during the restoration design process may have been feasible, had the objectives been different. This study has demonstrated that at Swindale over the last 1000 years there was a trajectory of river styles from braiding over a wandering planform to single-thread with episodes of impoundment which can be linked with historic changes in climate and sediment supply. Hence, this fluvial system appears to be relatively responsive to extrinsic changes. This is an important consideration when creating channel configurations that are sustainable and functional in predicted climate change conditions. While the gaps in our survey, largely imposed by recent engineering works, prevented the reconstruction of a coherent channel network for the individual stages of development, GPR surveys can be used to create three-dimensional subsurface models (e.g. [Heinz](#page-18-0) and [Aigner,](#page-18-0) 2003; Kostic and [Aigner,](#page-18-0) 2007) which may serve as a basis for hydraulic modelling of flow and sediment conveyance for comparison with planned restoration options. Whilst our results demonstrate clear evidence for a former multi-thread channel system at the study site, we do not claim that this is necessarily suitable for the current river system. However, knowledge of past river styles gained from GPR data may help to select an appropriate channel morphology that is aligned with the contemporary and future flood and sediment supply regime and may go beyond the often aesthetically favoured meandering design [\(Podolak](#page-19-0) and [Kondolf,](#page-19-0) 2016). Additionally, in wider river management context,

the appreciation of the sedimentary consequences of past anthropogenic actions (e.g., channel straightening in stage 5) for the floodplain may support adaptive planning for prospective works (e.g., water diversions) ([Lewin,](#page-18-0) 2013).

Secondly, for river restoration programs knowing the precise position, depth and thickness of gravel/ cobble bodies in the floodplain allows dimensioning and positioning of restored channels ([Schneider](#page-19-0) et al., [2011\)](#page-19-0). The presented GPR data distinguished between grain size fractions of sediment and precisely outlined former channels which could be linked in many instances. This investigation also shows that many of the palaeochannels were not evident from aerial photography or lidar commonly used for their detection, or masked by engineering works of stage 5. At Swindale the routing of the new channel of the restoration scheme was in the lower part of the study site (around areas A, B and C) guided by the presence of channels on the floodplain interpreted from lidar and aerial photography while in the upper part (areas D, E and F) a more sinusoidal course was favoured. The postrestoration channel development (stage 6, Fig. 13) shows for the latter a lower level of channel dynamics and [Wightman](#page-19-0) and Schofield (2021) noted a paucity of gravels in the restored channel. A GPR survey across the site before the restoration works would have enabled identification of the location of single-thread or low order multi-thread channels of stage 4, their connectivity at depth and dimensions and thus may have avoided the need to artificially construct gravel bars.

Thirdly, spatially coherent information on floodplain stratigraphy reveals location and quantity of sustainable and local sources of coarse substrate potentially needed during restoration works (e.g., sediment replenishment), which are as cut-and fill structures often not evident from surface topography ([Huber](#page-18-0) et al., 2019). GPR surveys can also indicate suitable conditions for wetlands ([Szuch](#page-19-0) et al., 2006) and characterise gravel aquifers [\(Doetsch](#page-18-0) et al., 2010, 2012). Furthermore, they allow avoidance of undesired sedimentary bodies (e.g., mining deposits, landfill) and the, often neglected, assessment of vertical hyporheic connectivity [\(Sparacino](#page-19-0) et al., 2019; [Howard](#page-18-0) et al., 2024).

Floodplain roughness and vegetation have been shown to impose some limits on efficient surveying and thick and clay rich top layers may attenuate the radar signal and reduce penetration depth [\(Annan,](#page-17-0) 2008). Nevertheless, our results clearly demonstrate that in suitable conditions and particularly for larger areas, GPR surveys can provide a more spatially coherent, non-invasive imaging of the floodplain compared to coring and can be a valuable tool to guide the river restoration practitioner towards recreating an appropriate channel morphology.

#### <span id="page-17-0"></span>**7. Conclusions**

This study demonstrates the utility of GPR surveys to identify floodplain evolution and spatio-temporal river planform development at Swindale Beck under the influence of various conditioning factors such as bedrock geology, glacial deposits, activity of alluvial fans and anthropogenic activity. This led to the reconstruction of five main stages of floodplain development over the entire study site with an additional stage for the south-eastern part where alluvial fan activity appears to have triggered a more complex drainage pattern. OSL dating placed the transition from a braiding river style to a dominantly wandering planform within the last 990 years. The response of river planform to the conditioning influences in such a timeframe is relevant for river restoration schemes which aim to create sustainable conditions in a changing climate. Thus, we argue that understanding of past river styles, which can be efficiently obtained from GPR surveys, provides practitioners with important information for deciding design options. For the example of Swindale it is demonstrated how subsurface imaging also allows appraisal of hyporheic connectivity, location of gravel resources and identification of depth and geometry of a wider range of palaeochannels than can be obtained from surface data. While a full absolute chronology for each stage of development was not permitted with the design of OSL sampling and thus beyond the scope of this paper, it would be desirable for linking past environmental conditions with the corresponding geomorphological processes at each stage. Furthermore, closer spacing of GPR survey profiles and data acquisition prior to fragmentation of the floodplain by restoration works may allow for better reconstruction of palaeotopography. This may in turn serve as a basis for hydrodynamic modelling in order to test the suitability of past river styles under contemporary sedimentary and hydrological conditions.
