1 **Abstract**

2 Long-term implications of acutely increased cardiorespiratory fitness following short-term  
3 exercise interventions in older adults are unknown. In this study, we examined peak oxygen  
4 uptake ( $VO_{2peak}$ ) after four years of 'free-living' after a high intensity interval training (HIIT)  
5 intervention. Seventeen lifelong exercisers (LEX) and 17 previously sedentary (SED) males  
6 (55–74 years of age in 2012) were tested four years (phase D) after our previous experiment  
7 which included 6-weeks of aerobic moderate intensity exercise (phase B), followed by 6-weeks  
8 of HIIT (phase C). At all stages, a standard incremental exercise protocol on a cycle ergometer  
9 was completed to determine  $VO_{2peak}$ . SED ( $P=1.000$ , Cohen's  $d=0.01$ ) and LEX ( $P=1.000$ ,  
10 Cohen's  $d=0.11$ )  $VO_{2peak}$  at phase D was not different from phase A (enrolment). SED  
11 experienced a large decrease in  $VO_{2peak}$  from phase C to phase D ( $32 \pm 6$  ml·kg·min<sup>-1</sup> to  $27 \pm$   
12  $6$  ml·kg·min<sup>-1</sup> [ $P<0.001$ , Cohen's  $d=0.81$ ]). LEX experienced a small decrease in  $VO_{2peak}$  from  
13 phase C to phase D ( $42 \pm 7$  ml·kg·min<sup>-1</sup> to  $39 \pm 9$  ml·kg·min<sup>-1</sup> [ $P<0.001$ , Cohen's  $d=0.46$ ]). At  
14 phase D, LEX had greater  $VO_{2peak}$  than SED ( $P<0.001$ , Cohen's  $d=1.73$ ). The proportion of  
15 subjects who reported discontinuing training, maintaining moderate training, and maintaining  
16 HIIT differed between groups ( $P=0.023$ ), with LEX self-reporting more HIIT, and SED self-  
17 reporting more discontinuation from exercise. Those who continued exercising experienced a  
18 reduction in  $VO_{2peak}$  over the four years from  $39 \pm 7$  ml·kg·min<sup>-1</sup> to  $36 \pm 9$  ml·kg·min<sup>-1</sup> ( $N=25$ ,  
19  $P<0.001$ , Cohen's  $d=0.37$ ), and those who discontinued exercising also experienced a reduction  
20 in  $VO_{2peak}$  from  $30 \pm 7$  ml·kg·min<sup>-1</sup> to  $25 \pm 9$  ml·kg·min<sup>-1</sup> ( $N=9$ ,  $P=0.003$ , Cohen's  $d=0.62$ ).  
21 Four years after completing a brief period of aerobic exercise and HIIT, older males  
22 demonstrated a preservation of  $VO_{2peak}$ , irrespective of training status (LEX or SED). However,  
23 LEX exhibited greater  $VO_{2peak}$  than SED after 4-years of unsupervised 'free-living'. Finally,  
24 those who discontinued exercising experienced a greater reduction in  $VO_{2peak}$ . These findings  
25 infer that to maintain aerobic capacity, 6 weeks of HIIT every four year may be sufficient, but  
26 to attenuate the decline, exercise should be maintained.

## 1 **1 Introduction**

2 Biological ageing is characterised by a progressive loss of physical function and increased risk  
3 of developing various common diseases, including cardiovascular disease (CVD), type II  
4 diabetes, and many cancers (Butler et al., 2008). Indeed, cardiovascular fitness is a powerful  
5 predictor of loss of independence (de Oliveira Brito et al., 2014), and risk of morbidity (Blair  
6 et al., 1989; Seccareccia and Menotti, 1992) and mortality (Imboden et al., 2018). Thus, the  
7 decline in physiological function that accompanies advancing age presents a major obstacle to  
8 achieving increased health span (Beard and Bloom, 2015), the phase of life without disability  
9 and free from serious chronic diseases (Seals and Melov, 2014). Lifestyle interventions capable  
10 of ameliorating the deleterious changes in physiological system (e.g. muscular, cardiovascular,  
11 endocrine, immune, to name but a few) associated with chronological ageing will prolong the  
12 health span (Seals and Melov, 2014), whilst also reducing risk of age-related CVD (Chiao and  
13 Rabinovitch, 2015). One such strategy is physical activity, with recent meta-analytical work  
14 demonstrating running activities were associated with a 30% reduction in cardiovascular  
15 mortality (Pedisic et al., 2019). This corroborates the recently published narrative by the United  
16 Kingdom government, identifying a curvilinear dose-response relationship between physical  
17 activity and health outcomes (UK Chief Medical Officers' report). Furthermore, exercise has  
18 been proposed as a countermeasure to biological ageing in humans, whereby physically active  
19 humans are phenotypically younger than sedentary counterparts, or where individuals display  
20 a 'younger' phenotype as a result of exercise training (Beaumont et al., 2019; Campbell et al.,  
21 2019; Elliott et al., 2017; Hayes et al., 2015a, 2015b; Mcleod et al., 2019; Piasecki et al., 2019;  
22 Sellami et al., 2019, 2018, 2017; Stenbäck et al., 2019a, 2019b). Moreover, the 'masters athlete'  
23 – broadly defined as an individual older than 45 or 50 years of age involved with competitive  
24 exercise (D'Andrea et al., 2007; Wilson et al., 2010) – represents a non-pharmacological model  
25 to isolate the inexorable from the preventable declines in cardiovascular ageing (Beaumont et  
26 al., 2018).

27 One characteristic of advancing age is a reduced peak oxygen uptake ( $VO_{2peak}$ )  
28 (Astrand, 1960; Beaumont et al., 2020; Dill et al., 1967; Rogers et al., 1990). This decrease  
29 accelerates with age (Hawkins and Wiswell, 2003) such that there is a ~16% decrease across  
30 the fifth decade but a ~26% decrease during the seventh decade and above (Fleg et al., 2005).  
31 Indeed, lower levels of cardiorespiratory fitness are associated with an increased risk of  
32 cardiovascular and all-cause mortality (Imboden et al., 2018; Paffenbarger et al., 1993).  
33 Although decreased  $VO_{2peak}$  with increased age occurs irrespective of training status (Pimentel  
34 et al., 2003), the *rate* of decline may be "flattened" through exercise training, as masters athletes  
35 exhibit less  $VO_{2peak}$  loss over 8 years than sedentary counterparts (Rogers et al., 1990). This  
36 "flattened" decline with regular training becomes important given that small improvements in  
37 cardiorespiratory fitness have a disproportionately large impact on health and survival  
38 (Kaminsky et al., 2013b; Kodama et al., 2009). Although these studies report improved health  
39 and fitness with regular exercise training over the life course, sedentary individuals who take-  
40 up exercise later in life may also achieve considerable health benefits (Knowles et al., 2015).

41 Despite convincing evidence for improved cardiorespiratory fitness as a consequence  
42 of engaging in short term exercise (Esfandiari et al., 2014; Grace et al., 2018; Knowles et al.,  
43 2015), long-term implications of these benefits in older adults are unclear. Whilst a supervised  
44 exercise intervention is known to improve cardiorespiratory fitness, the longer-term effect of  
45 this during subsequent unsupervised years is unknown.

46 In 2012, we completed a study of adaptation to low-volume high intensity interval  
47 training (HIIT) in older lifelong exercising (LEX) masters athletes and age matched  
48 longstanding sedentary (SED) men (Grace et al., 2015; Knowles et al., 2015). On completion,  
49 participants were provided with a detailed summary of their cardiovascular and metabolic  
50 health and returned to the community. Apart from this debrief and an open offer of advice from

1 the lead investigator, there was no formal support. The present study attempted to address the  
 2 dearth of information regarding legacy effects of training interventions by presenting a follow-  
 3 up of our previous work (Knowles et al., 2015). In medicine, a legacy effect, first discussed by  
 4 Holman et al. (2008) describes the lasting benefit of a treatment long after cessation of said  
 5 treatment (Coppo, 2013).

6 Therefore, the aim of the present investigation was to examine the legacy effect of 6-  
 7 weeks of conditioning exercise followed by 6-weeks of supervised HIIT, on cardiorespiratory  
 8 fitness after 4 years of ‘free-living’. We examined  $VO_{2peak}$  4 years later, in a ‘reunion’ study to  
 9 ascertain long-term implications. We hypothesised 1) both groups would experience a decline  
 10 in  $VO_{2peak}$ , 2) LEX would experience less of a decline in  $VO_{2peak}$ , and 3)  $VO_{2peak}$  would be  
 11 greater in LEX compared to SED at follow up.

## 12 2 Materials and Methods

### 13 2.1 Participants

14 In 2012, we recruited 39 participants aged 55–74 years from a random sample of the local  
 15 community to participate in a HIIT study (participant descriptions in **Table 1**). To be eligible,  
 16 participants were required to be healthy and have no medical conditions liable to contraindicate  
 17 the training programme. Following approval to exercise by their general practitioner,  
 18 participants provided informed written consent prior to the study which was approved by the  
 19 University of the West of Scotland and the University of Wales ethics committees. The  
 20 investigation adhered to the declaration of Helsinki. A SED and LEX group participated in the  
 21 study as previously described (Grace et al., 2018; Hayes et al., 2020; Knowles et al., 2015). In  
 22 2016, participants were invited to participate in a reunion study to identify changes in  
 23 cardiorespiratory fitness. These participants were not informed of a follow-up study during the  
 24 original investigation in 2012 and thus, were only invited back a few weeks prior to the  
 25 scheduled testing in 2016. The same inclusion criteria were used as for the 2012 assessments.  
 26 SED participants had not participated in organised exercise programmes for >30 years prior to  
 27 enrolment in the 2012 study. The LEX group were highly active exercisers and had been so for  
 28 the previous >30 years. They consisted of current masters athletes in sports including water-  
 29 polo, triathlon, track cycling, road cycling, and distance running. Participants arrived in the  
 30 exercise physiology laboratory between the hours of 07.00–09.00 h, following an overnight  
 31 fast and having abstained from strenuous exercise for a minimum of 48 h. Participants were  
 32 reminded to maintain standardised conditions prior to each assessment point which included  
 33 arriving in a hydrated state having abstained from caffeine and alcohol consumption for 36 h.  
 34

35 **Table 1:** Participant characteristics at baseline. SED = lifelong sedentary older males. LEX =  
 36 lifelong exercising older males.  $VO_{2peak}$  = Peak oxygen uptake. \*Different to SED at the  $P < 0.05$   
 37 level.

| Peak power output (W·kg <sup>-1</sup> )                | 7.7 ± 1.6            | 9.7 ± 1.8*           |

### 39 2.2 Peak oxygen uptake determination

1 Peak oxygen uptake was determined using a Cortex II Metalyser 3B-R2 (Cortex, Biophysik,  
2 Leipzig, Germany) utilising methods previously described (Knowles et al., 2015) and a  
3 modified Storer Test (Storer et al., 1990) on an air-braked cycle ergometer (Wattbike Ltd.,  
4 Nottingham, UK). Coefficient of variation for  $\text{VO}_{2\text{peak}}$  determination in our laboratory is  $<3\%$ ,  
5 and the metabolic equipment was serviced and maintained according to manufacturer's  
6 recommendations. The same equipment was used at all testing phases. Cycle ergometers were  
7 numbered, and each participant used the same ergometer for training and testing at all time  
8 points. Manufacturer reliability has been specified as  $\pm 2\%$  across the full power range.

9

### 10 2.3 Body composition determination

11 Stature was measured to the nearest 0.1 cm using a stadiometer (Seca, Birmingham, UK), and  
12 body mass and body composition was determined by a multi frequency bioelectrical impedance  
13 analyser (BIA [Tanita MC-180MA Body Composition Analyser, Tanita UK Ltd.]). GMON  
14 software (v1.7.0, Tanita UK Ltd.) was used to determine absolute and relative body fat. Fat  
15 free mass (FFM) was calculated by subtracting fat mass from total body mass.

16

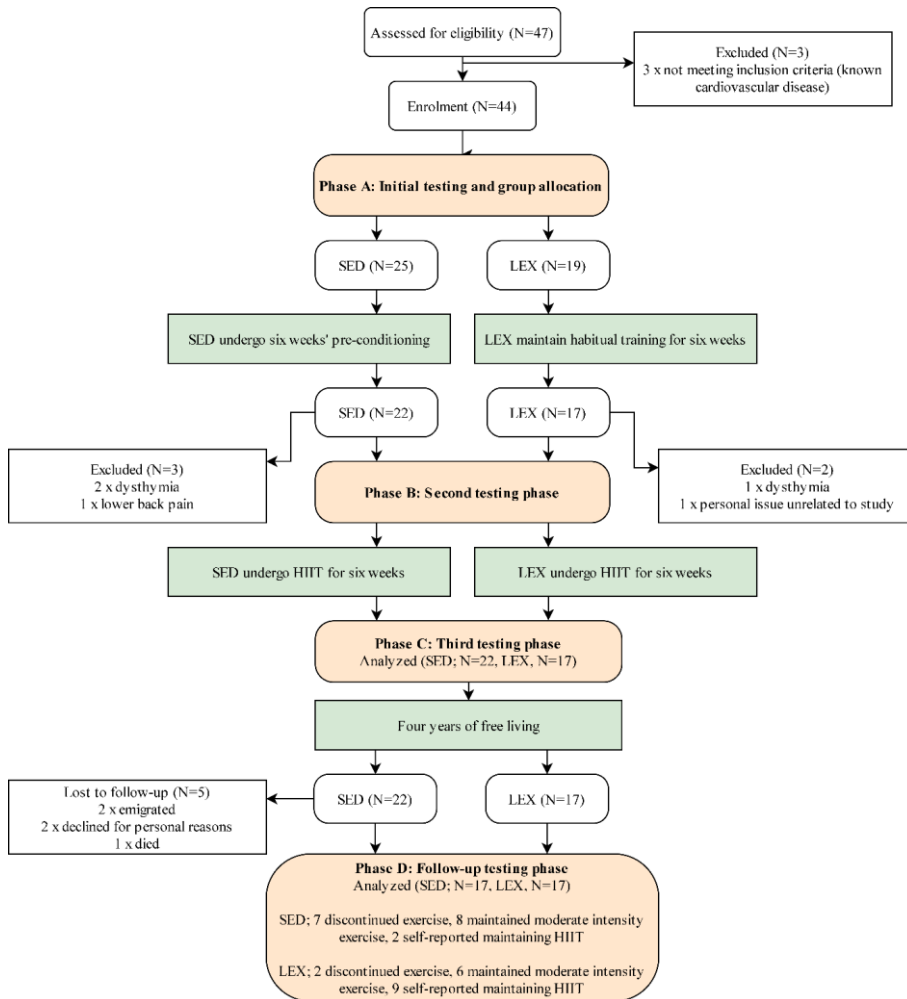

### 17 2.4 Exercise training

18 To account for the contribution of aerobic conditioning exercise in SED, participants were  
19 initially tested at three phases in 2012 (A, B, and C; **Figure 1**), which were interspersed with  
20 two six week training blocks as previously described (Knowles et al., 2015). Briefly, training  
21 block 1 (between phase A and B) consisted of moderate aerobic training amounting to 150  
22  $\text{min}\cdot\text{wk}^{-1}$  for the SED group, in line with the physical activity guidelines (Garber et al., 2011).  
23 During this time, LEX maintained their current training, which allowed us to capture training  
24 volumes and intensities. SED completed a minimum of two sessions per week. Participants  
25 were given verbal instructions on the use of a Polar FT1 heart rate monitor (Polar, Kempele,  
26 Finland) and exercise intensities were self-monitored, enabling recording of exercise time, and  
27 average and peak heart rate (exercise was unsupervised, but heart rate was checked). The aim  
28 was to achieve an average heart rate reserve (HRR [(Karvonen and Vuorimaa, 1988)]) of  
29 approximately 55% for the first two weeks of the intervention. This was increased to 60% HRR  
30 for the subsequent weeks including 5-10 s of increased intensity (prescribed as 'vigorous' in  
31 line with the ACSM guidelines (Garber et al., 2011)) every 10 min. The final two weeks  
32 included brief periods of exercise which elicited a HRR of 60-65% every 5 min. The mode of  
33 training was optional, and included walking, jogging, and cycling. During the six-weeks of  
34 preconditioning, SED exercised for  $160 \pm 15 \text{ min}\cdot\text{wk}^{-1}$ . Heart rate was recorded, using %HRR  
35 as a determinant of exercise intensity. Exercise training logs, including heart rate data, were  
36 submitted to the research team on a weekly basis to ensure participants adhered to instructions.  
37 If required, interventions were amended, ensuring intensity and duration were achieved. No  
38 nonexercise component (e.g. dietary guidance) was provided and no adverse events occurred,  
39 according to self-reporting, when questioned at each training session by the lead researcher.  
40 Whilst SED underwent preconditioning, LEX maintained their habitual training (unsupervised)  
41 which totalled  $281 \pm 144 \text{ min}\cdot\text{wk}^{-1}$  structured training. Exercise type, frequency, intensity  
42 (recorded by heart rate telemetry), and duration of training was recorded.  $214 \pm 131 \text{ min}\cdot\text{wk}^{-1}$   
43 and  $67 \pm 52 \text{ min}\cdot\text{wk}^{-1}$  was spent at  $<65\%$  HRR, and  $>65\%$  HRR respectively.

44 Both groups underwent HIIT from phase B to C (training block 2). HIIT was performed  
45 on a cycle ergometer (Wattbike Ltd., Nottingham, UK) every five days, for six weeks (nine  
46 sessions in total). Rationale for this frequency comes from our previous work which identified

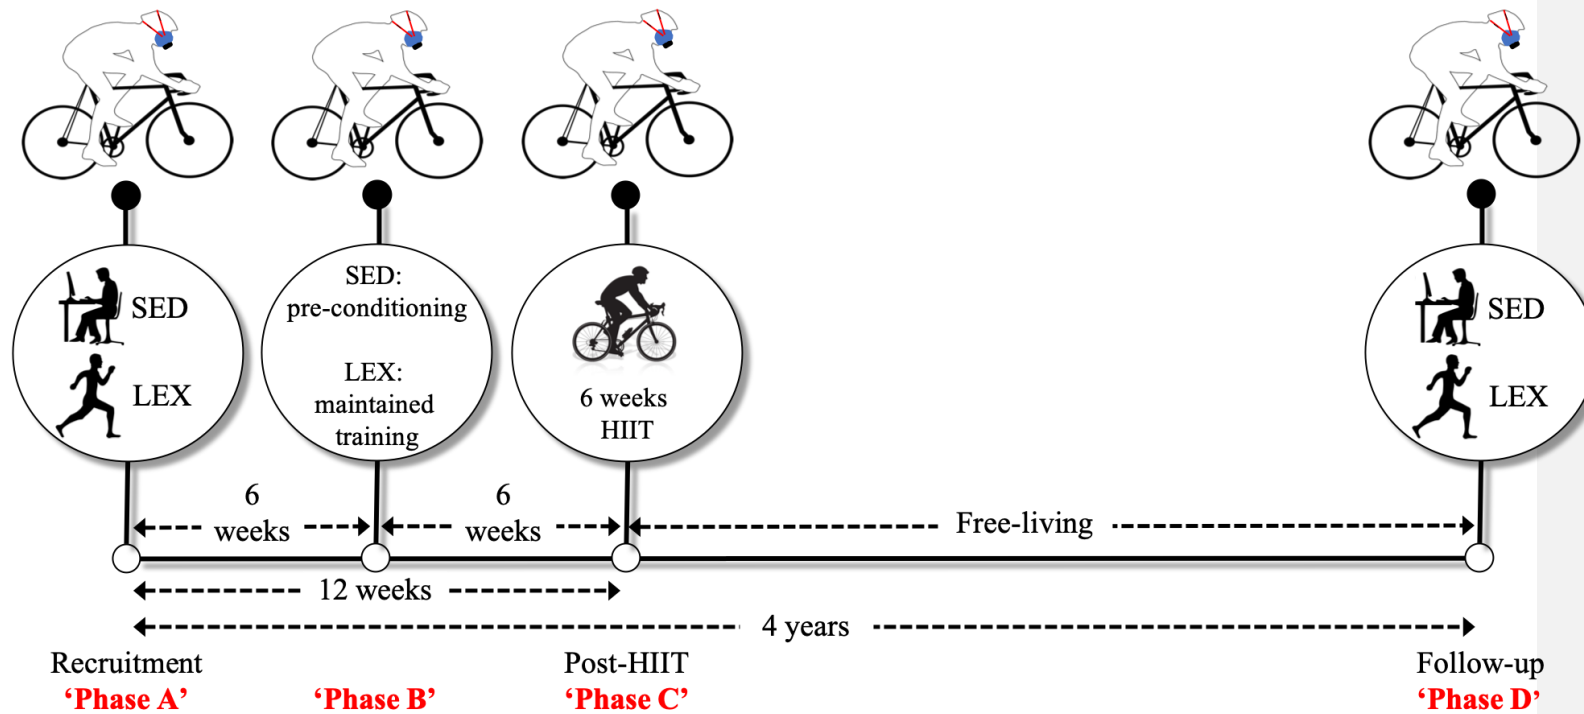

1 five days of rest was required for recovery of peak power output (PPO) following HIIT in older  
2 males (Herbert et al., 2015a). Sessions consisted of 6 x 30 s sprints at 40% PPO, with a cadence  
3 between 75 rpm and 100 rpm, interspersed with 3 min active recovery. Rationale for this  
4 intensity comes from our previous work which demonstrated this protocol achieved >90%HRR  
5 in a similarly aged cohort, and achieved improvements in muscle power (Sculthorpe et al.,  
6 2017) which is imperative in ageing cohorts (Manini and Clark, 2012). Sessions were  
7 conducted in groups of 4-6, supervised by a member of the research team in an exercise  
8 physiology laboratory. HIIT was conducted according to participants' availability, but  
9 primarily during traditional working hours (i.e. 09.00-17.00 h). No adverse events were  
10 reported, and no nonexercised component (i.e. nutritional guidance) was provided. During this  
11 phase, HIIT was the sole exercise performed by both groups.

12 Phase D was completed 4 years later, using identical testing methods but without  
13 supervised training in the intervening 4 years (**Figure 2**). At follow-up (phase D), participants  
14 provided a current training diary. This included whether they were competing in masters  
15 events, the type of training (moderate aerobic conditioning, HIIT, and/or resistance training),  
16 and the training volume per week, in minutes.

1  
2 **Figure 1:** The CONSORT (Consolidated Standards of Reporting Trials) flow chart depicting  
3 transition of lifelong sedentary (SED) and lifelong exercising (LEX) participants through the  
4 study. HIIT = high intensity interval training.

1  
2  
3  
4  
5  
6  
7

**Figure 2:** Peak oxygen uptake ( $VO_{2peak}$ ) was determined at Phases A, B, C and D. Sedentary (SED) vs. lifelong exercisers (LEX) were compared at Phase D in their original groupings determined in Phase A. Phase A-B, 6 week intervention period whereby SED conducted pre-conditioning exercise and LEX maintained normal training; Phase B-C, 6 weeks high-intensity interval training (HIIT) in both LEX and SED; Phase C-D, period of free-living without intervention; Phase A- D, 4-year follow-up period.

1  
2 2.5 Statistical Analysis  
3 Data were analysed using Jamovi version 1.6.16. Following a Shapiro-Wilk test of normality  
4 and Levene's test for homogeneity of variance, a two-way (group [SED, LEX] x phase [A, B,  
5 C, D]) mixed factorial analysis of variance (ANOVA) was conducted to test for differences  
6 between groups and time points. Subsequently, *posteriori* T-tests with Bonferroni correction  
7 were conducted to determine differences between groups and between phases. A chi-square  
8 tested for differences in training habits between LEX and SED. To establish the effect of  
9 continuing or discontinuing exercise, a two-way (exercise habit ['continuer', 'discontinuer'] x  
10 phase [A, B, C, D]) mixed factorial ANOVA was conducted. Subsequently, *posteriori* T-tests  
11 with Bonferroni correction were conducted to determine differences between groups (unpaired  
12 T-tests) and between phases (paired T-tests). Alpha level is reported as exact P values as  
13 suggested by Hurlbert et al. (2019) and effect size for paired comparisons is reported as Cohen's  
14 *d* whereby the difference in means between two samples was divided by the pooled standard  
15 deviation (SD). Thresholds of 0.15, 0.40, and 0.75 for *Cohen's d* were interpreted as small,  
16 moderate, and large as these are appropriate in gerontology (Brydges, 2019). The analysis will  
17 primarily deal with comparisons between phase A (enrolment) and D (follow up), and phase C  
18 (post-HIIT) and D, consistent with other reunion studies (Johnson et al., 2019). Data are  
19 presented as mean  $\pm$  standard deviation (SD) in text and figures are presented as grouped dot  
20 plots, as recommended by Drummond and Vowler (2012).

21  
22

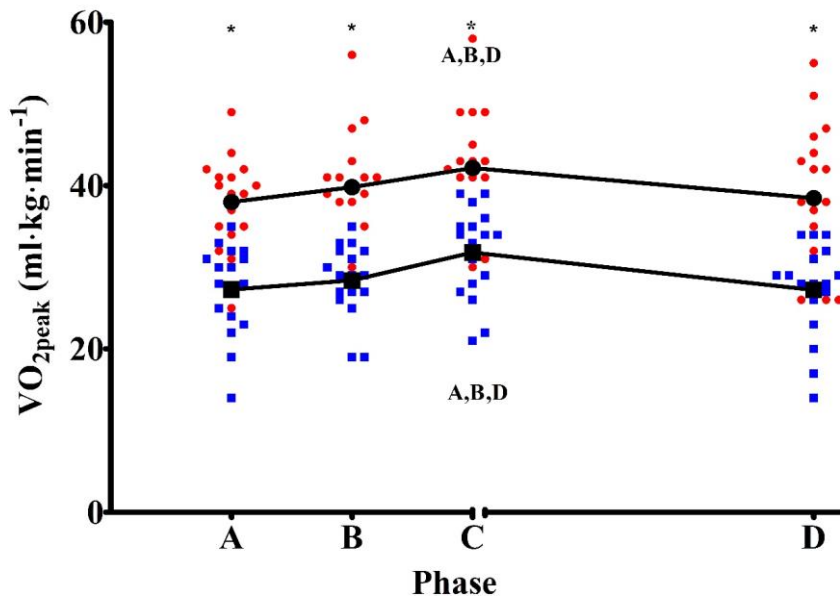

### 23 3 Results

#### 24 3.1 Peak oxygen uptake

25  $VO_{2peak}$  data have been previously reported for phases A, B, and C of the original study  
26 (Knowles et al., 2015). Briefly, both LEX and SED improved relative and absolute  $VO_{2peak}$   
27 following HIIT, and LEX  $VO_{2peak}$  was greater than SED  $VO_{2peak}$  at all phases (all  $P < 0.05$ ).

28 There was a main effect of time ( $P < 0.001$ ), and group ( $P < 0.001$ ) on relative  $VO_{2peak}$ .  
29 However, there was no interaction between group and time ( $P = 0.313$ ). SED  $VO_{2peak}$  was  $27 \pm$   
30  $6 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  at enrolment (phase A), which increased post-HIIT ( $32 \pm 6 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  at phase  
31 C;  $P < 0.001$ , Cohen's  $d = 0.81$ ). Subsequently, SED  $VO_{2peak}$  decreased to  $27 \pm 6 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  at  
32 phase D ( $P < 0.001$ , Cohen's  $d = 0.81$  compared to C). Importantly, SED  $VO_{2peak}$  at phase D was  
33 not different from phase A ( $P = 1.000$ , Cohen's  $d = 0.01$ ) or B ( $P = 0.234$ , Cohen's  $d = 0.23$ ). LEX  
34  $VO_{2peak}$  was  $38 \pm 6 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  at enrolment (phase A), which was increased post-HIIT ( $42 \pm$   
35  $7 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  at phase C;  $P < 0.001$ , Cohen's  $d = 0.67$ ). Subsequently, LEX  $VO_{2peak}$  decreased to  
36  $39 \pm 9 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  at phase D ( $P < 0.001$ , Cohen's  $d = 0.46$  compared to C). LEX  $VO_{2peak}$  at  
37 phase D was not different from phase A ( $P = 1.000$ , Cohen's  $d = 0.11$ ) or B ( $P = 1.000$ , Cohen's  
38  $d = 0.15$ ).  $VO_{2peak}$  was lower in SED compared to LEX at phase D ( $P < 0.001$ , Cohen's  $d = 1.73$ ).

39 In terms of absolute  $VO_{2peak}$ , results were concomitant with relative  $VO_{2peak}$  in that there  
40 was a main effect of time ( $P < 0.001$ ), and group ( $P < 0.001$ ). However, there was no interaction  
41 between group and time ( $P = 0.641$ ). SED  $VO_{2peak}$  was  $2.38 \pm 0.33 \text{ l}\cdot\text{min}^{-1}$  at enrolment (phase  
42 A), which increased post-HIIT ( $2.80 \pm 0.47 \text{ l}\cdot\text{min}^{-1}$  at phase C;  $P < 0.001$ , Cohen's  $d = 1.03$ ).  
43 Subsequently, SED  $VO_{2peak}$  decreased to  $2.39 \pm 0.46 \text{ l}\cdot\text{min}^{-1}$  at phase D ( $P < 0.001$ , Cohen's  
44  $d = 0.88$  compared to C). Importantly, SED  $VO_{2peak}$  at phase D was not different from phase A  
45 ( $P = 1.000$ , Cohen's  $d = 0.02$ ) or B ( $P = 1.000$ , Cohen's  $d = 0.28$ ). LEX  $VO_{2peak}$  was  $3.08 \pm 0.50$   
46  $\text{l}\cdot\text{min}^{-1}$  at enrolment (phase A), which was increased post-HIIT ( $3.43 \pm 0.52 \text{ l}\cdot\text{min}^{-1}$  at phase C;  
47  $P < 0.001$ , Cohen's  $d = 0.69$ ). Subsequently, LEX  $VO_{2peak}$  decreased to  $3.14 \pm 0.55 \text{ l}\cdot\text{min}^{-1}$  at  
48 phase D ( $P = 0.003$ , Cohen's  $d = 0.54$  compared to C). LEX  $VO_{2peak}$  at phase D was not different  
49 from phase A ( $P = 1.000$ , Cohen's  $d = 0.17$ ) or B ( $P = 1.000$ , Cohen's  $d = 0.05$ ). Absolute  $VO_{2peak}$   
50 was lower in SED compared to LEX at phase D ( $P < 0.001$ , Cohen's  $d = 1.48$ ).

2  
3 **Figure 3:** Peak oxygen uptake ( $VO_{2peak}$ ), in a group of sedentary (SED; blue squares) and  
4 lifelong exercising (LEX; red circles) older males. Data are presented as means plus individual  
5 data points. \*Denotes differences between groups at this experimental phase at the  $P < 0.05$   
6 level. A = Different from phase A at the  $P < 0.05$  level. B = Different from phase B at the  $P < 0.05$   
7 level. D = Different from phase D at the  $P < 0.05$  level.

8  
9 The proportion of subjects who reported discontinuing training, maintaining moderate  
10 training, and maintaining HIIT differed between groups ( $P = 0.023$ ), with LEX self-reporting  
11 more HIIT, and SED self-reporting more discontinuation from exercise. As there were not  
12 enough SED participants who continued HIIT, and not enough LEX participants who  
13 discontinued exercise, we pooled these data into two groups; those who continued to exercise  
14 ( $N = 25$ ; 15 LEX), and those who discontinued exercise ( $N = 9$ ; 2 LEX) in the four years of free  
15 living. When comparing relative  $VO_{2peak}$  at phase C and D, there was an effect of time  
16 ( $P < 0.001$ ), and exercise continuation (continued exercising or discontinued exercising;  
17  $P = 0.002$ ), but no interaction between exercise continuation and time [ $P = 0.399$ ]. In pairwise  
18 comparisons, those who continued exercising experienced a reduction in  $VO_{2peak}$  over the four  
19 years from  $39 \pm 7$  ml·kg·min<sup>-1</sup> to  $36 \pm 9$  ml·kg·min<sup>-1</sup> ( $N = 25$ ,  $P < 0.001$ , Cohen's  $d = 0.37$ ), and  
20 those who discontinued exercising also experienced a reduction in  $VO_{2peak}$  from  $30 \pm 7$   
21 ml·kg·min<sup>-1</sup> to  $25 \pm 9$  ml·kg·min<sup>-1</sup> ( $N = 9$ ,  $P = 0.003$ , Cohen's  $d = 0.62$ ). When examining the SED  
22 cohort only, there was an effect of time ( $P < 0.001$ ), and exercise continuation (continued  
23 exercising, discontinued exercising;  $P = 0.008$ ), but no interaction between exercise  
24 continuation and time ( $P = 0.755$ ). In *posteriori* Bonferroni corrected comparisons, those who  
25 continued exercise experienced a reduction in  $VO_{2peak}$  from  $35 \pm 3$  ml·kg·min<sup>-1</sup> at phase C to  
26  $30 \pm 3$  ml·kg·min<sup>-1</sup> at phase D ( $N = 10$ ,  $P < 0.001$ , Cohen's  $d = 1.05$ ), and those who discontinued  
27 exercising experienced a reduction in  $VO_{2peak}$  from  $28 \pm 6$  ml·kg·min<sup>-1</sup> at phase C to  $23 \pm 6$

1 ml·kg·min<sup>-1</sup> at phase D (N=7, P<0.001, Cohen's *d*=0.83). At phase A, SED 'continuers' VO<sub>2peak</sub>  
 2 was 29 ± 4 ml·kg·min<sup>-1</sup> and SED 'discontinuers' VO<sub>2peak</sub> was 25 ± 7 ml·kg·min<sup>-1</sup> (two-tailed  
 3 post hoc Bonferroni corrected T-test P=0.109, Cohen's *d*=0.84). At phase B, SED 'continuers'  
 4 VO<sub>2peak</sub> was 30 ± 3 ml·kg·min<sup>-1</sup> and SED 'discontinuers' was 26 ± 5 ml·kg·min<sup>-1</sup> (P=1.000,  
 5 Cohen's *d*=1.16). At phase C, SED 'continuers' VO<sub>2peak</sub> was 35 ± 3 ml·kg·min<sup>-1</sup> and SED  
 6 'discontinuers' was 28 ± 6 ml·kg·min<sup>-1</sup> (P=0.289, Cohen's *d*=1.42). At phase D, SED  
 7 'continuers' VO<sub>2peak</sub> was 30 ± 3 ml·kg·min<sup>-1</sup> and SED 'discontinuers' was 23 ± 6 ml·kg·min<sup>-1</sup>  
 8 (P=0.185, Cohen's *d*=1.47).

9 To further investigate the effect of the intervening four years on aerobic capacity, we  
 10 examined self-reported exercise intensity (n=14 moderate intensity exercise only and n=11  
 11 self-reported maintaining HIIT) on VO<sub>2peak</sub> from phase C to D. In this context, there was a main  
 12 effect of time (P<0.001), and intensity group (HIIT or moderate intensity [P<0.001]) on relative  
 13 VO<sub>2peak</sub>. There was an interaction between intensity group and time (P=0.012). HIIT group  
 14 VO<sub>2peak</sub> was 39 ± 5 ml·kg·min<sup>-1</sup> at enrolment (phase A), which increased post-HIIT (44 ± 7  
 15 ml·kg·min<sup>-1</sup> at phase C; P<0.001, Cohen's *d*=0.82). Subsequently, HIIT group VO<sub>2peak</sub> was  
 16 unchanged from C to D (43 ± 7 ml·kg·min<sup>-1</sup> at phase D; P=1.000, Cohen's *d*=0.14 compared to  
 17 C). In terms of magnitude, the HIIT group VO<sub>2peak</sub> at phase D was moderately increased from  
 18 phase A (P=0.081, Cohen's *d*=0.66). The moderate intensity group VO<sub>2peak</sub> was 31 ± 6  
 19 ml·kg·min<sup>-1</sup> at enrolment (phase A), which was greater post-HIIT (36 ± 5 ml·kg·min<sup>-1</sup> at phase  
 20 C; P<0.001, Cohen's *d*=0.90). Subsequently, the moderate intensity group VO<sub>2peak</sub> decreased  
 21 to 30 ± 7 ml·kg·min<sup>-1</sup> at phase D (P<0.001, Cohen's *d*=1.20 compared to C). Moderate intensity  
 22 group VO<sub>2peak</sub> at phase D was not different from phase A (P=1.000, Cohen's *d*=0.18) or B  
 23 (P=0.403, Cohen's *d*=0.54). VO<sub>2peak</sub> was lower in the moderate intensity group compared to the  
 24 HIIT at all phases (P≤0.038, Cohen's *d*≥1.30).

### 3.2 Body composition

27 Body composition in both groups at all phases is displayed in **table 2**. In brief, there was no  
 28 main effect of time (P=0.071) or group (P=0.143) on total body mass at the P<0.05 level.  
 29 However, there was an interaction between group and time (P=0.027). There was no main  
 30 effect of time (P=0.440), group (P=0.163), or interaction (P=0.689) on lean body mass at the  
 31 P<0.05 level. There was no main effect of time (P=0.156) on body fat percentage. However,  
 32 the effect of group (P=0.005), and interaction between group and time (P=0.014) did reach the  
 33 P<0.05 level.

34 **Table 2:** Body composition at phase A, B, C, and D in lifelong sedentary (SED) and lifelong  
 35 exercising (LEX) older males.  
 36

|                 | LEX (N=17)                  | SED (N=17)     |
|-----------------|-----------------------------|----------------|
| Total body mass |                             |                |
| Phase A         | 81.3 ± 12.4 kg              | 90.6 ± 17.8 kg |
| Phase B         | 81.0 ± 12.6 kg              | 89.6 ± 17.2 kg |
| Phase C         | 81.7 ± 12.6 kg              | 89.8 ± 18.1 kg |
| Phase D         | 83.5 ± 15.7 kg <sup>B</sup> | 89.8 ± 18.6 kg |
| Lean body mass  |                             |                |
| Phase A         | 62.9 ± 6.7 kg               | 63.7 ± 7.0 kg  |
| Phase B         | 62.0 ± 6.8 kg               | 63.4 ± 7.5 kg  |

|                     |               |               |
|---------------------|---------------|---------------|
| Phase C             | 62.2 ± 7.1 kg | 64.0 ± 8.3 kg |
| Phase D             | 62.8 ± 7.9 kg | 62.8 ± 8.1 kg |
| Body fat percentage |               |               |
| Phase A             | 18.9 ± 5.2%   | 26.4 ± 7.1%   |
| Phase B             | 19.5 ± 6.1%   | 25.5 ± 7.6%   |
| Phase C             | 19.9 ± 6.0%   | 24.9 ± 7.6%   |
| Phase D             | 20.5 ± 7.2%   | 25.8 ± 7.5%   |

<sup>B</sup>=different from phase B at the P<0.05 level.

#### 4 Discussion

In this reunion study, we evaluated changes in cardiorespiratory fitness 4 years after completing the original intervention, relative to assessments at enrolment. Accordingly, the present study represents the intervention-related changes plus those persisting over the intervening 4 years, aptly named the ‘legacy effect’. The main findings of this study are: (1) a short-term HIIT intervention which followed six weeks moderate intensity activity preserved  $VO_{2peak}$  over a four-year timespan, (2) lifelong exercise results in greater aerobic capacity than is achievable following a short-term HIIT intervention, (3) a short-term HIIT intervention resulted in half of the original SED group maintaining self-reported exercise adherence for four years, and (4) even in a group of highly motivated, life-long exercisers there is a attrition rate in terms of exercise engagement of 12% over 4 years. Taken together these findings indicate that short-term HIIT interventions can have substantial impacts on aerobic capacity, and by extension cardiovascular risk.

The finding that a short-term HIIT intervention can preserve  $VO_{2peak}$  over a four-year period is both novel and important. While the observation that LEX had greater cardiorespiratory fitness than LEX is not new, it is encouraging that irrespective of initial fitness levels, both groups exhibited a similar response pattern following short-term HIIT and then after 4-years of ‘free-living’. Few other studies have followed participants over such a long-time frame. Moreover, the lack of decline between Phase A and D is impressive given previous work. In the STRRIDE Reunion Study (Johnson et al., 2019),  $VO_{2peak}$  declined by ~10% from enrolment to 10 years follow-up, although the vigorous intensity training groups experienced only a ~5% decrease from pre-training to follow-up. This appeared primarily due to the 8 months of vigorous intensity training creating the greatest increase in  $VO_{2peak}$  (~10%, like the increase observed in our 12-week study). The obvious differences between the STRRIDE Reunion Study and this investigation was the difference in follow-up time (10 vs. 4 years, respectively), the difference in intervention duration (8 months vs 12 weeks, respectively), and the type of intervention (aerobic conditioning vs aerobic conditioning and HIIT). However, despite differences, both Johnson et al (2019), and we surmise that a short-term exercise intervention has significant legacy effects for cardiorespiratory fitness, which may be intensity dependent. The seminal work of Rogers et al. (1990) reported that in the absence of a training regime, sedentary individuals can expect to lose 10% of their aerobic capacity over an 8-year period. The same data would therefore predict a 5% decline in  $VO_{2peak}$  across the 4 years of our follow-up data which was not the case. One criticism of short-term interventions is the tendency to demonstrate large effect sizes over the short term during supervised, laboratory based interventions, which may not be sustained over the longer term, or may be reduced once moved out of a controlled laboratory setting, often termed the ‘voltage drop’ of interventions (Chambers et al., 2013; Kilbourne et al., 2007). The present data supports

1 this view, since the intervention resulted in initial increases in aerobic capacity, which were  
2 lost over the 4-years.

3 Despite the 'free living' nature of the follow up period, most previously sedentary  
4 participants remained engaged with some form of regular exercise and prevented further  
5 declines relative to their original  $VO_{2peak}$ . Considering cardiorespiratory fitness is an  
6 independent predictor of all-cause mortality (Kodama, 2009), and that small increases  
7 correspond to large reductions in CVD risk (Kaminsky et al., 2013a) these observations have  
8 important implications for the role of exercise prescription in managing aerobic capacity and  
9 CVD risk in advancing age. Furthermore, although this investigation concerned  $VO_{2peak}$   
10 exclusively, it would be expected that the maintenance of fitness would likely be associated  
11 with improved blood pressure, cholesterol, and other CVD risk factors. Future studies should  
12 explore whether the extent of this protection extends beyond 4 years. If we assume the rate of  
13 decline in the LEX group represents the best possible outcome, it is feasible that the SED group  
14 could maintain their level of fitness for a decade or more. In addition, future work should also  
15 investigate the influence of variations in HIIT protocols.

16 There are additional important findings from this study which also warrant further  
17 discussion. Aside from the intervention, our original study provided no additional access to  
18 supervised exercise or sport participation. However, the lead investigator did offer to provide  
19 ongoing advice to any participants who requested it. Considering this, the adherence rate of  
20 59% is substantial given that it was not an aim in the original investigation. The reason for the  
21 relatively high adherence is unclear. The lead investigator (PH) is a member of the local  
22 community from which participants were recruited, and a local advocate for healthy ageing. It  
23 may be that being known in the community, combined with regular advice contributed to the  
24 higher adherence than anticipated, and future qualitative work will investigate this hypothesis.  
25 Conversely, it may be that the early introduction of HIIT, and the increase in aerobic capacity  
26 at Phase C resulted in participants feeling more able to take part moderate to high intensity  
27 exercise and removed their fear of participation. Previous work indicated that HIIT in this age  
28 group resulted in reductions in pain and increase in general health (Knowles et al., 2015).  
29 Others have also reported that sedentary participants find HIIT more enjoyable than moderate  
30 intensity exercise (Bartlett et al., 2011; Thum et al., 2017). It is plausible therefore that together,  
31 these factors may have contributed to the relatively high exercise adherence over the 4-years.  
32 Our hypothesis that greater aerobic capacity at phase C as a result of HIIT resulted in greater  
33 likelihood of exercise participation in the subsequent four years is supported by comparison  
34 between 'continuers' and 'discontinuers'. We observed that individuals classified as 'continuers'  
35 of exercise in the four years of free living had a greater  $VO_{2peak}$  at enrolment (phase A) and  
36 throughout the experiment. Although this was not at the  $P < 0.05$  level, the large effect size and  
37 difference of  $>1$  MET ( $3.5 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$ ) at all phases suggest this was a clinically meaningful  
38 difference. Interestingly, continuers had a greater aerobic capacity than discontinuers, and they  
39 were more responsive to the HIIT stimulus (i.e. the difference in  $VO_{2peak}$  between phase A and  
40 phase C) was greater in continuers compared to discontinuers ( $5.3 \text{ ml}\cdot\text{kg}\cdot\text{min}^{-1}$  vs.  $3.3$   
41  $\text{ml}\cdot\text{kg}\cdot\text{min}^{-1}$  respectively), suggesting that absolute fitness, but also adaptation to training, may  
42 underpin increased exercise participation.

43 A final unanticipated finding of the present study was that the attrition rate in the LEX  
44 group was higher than anticipated at 12% across the 4 years. Given that this group were  
45 originally included to act as a positive control, they represent a cohort of individuals who have  
46 a strong and persistent drive to exercise and maintain physical fitness and are likely therefore,  
47 to represent the greatest degree of adherence possible in this age group. While admittedly in a  
48 relatively small cohort, the present data suggests the best adherence realistically achievable in

1 free-living studies. Thus, the 59% adherence of the SED group in this study, and adherence in  
2 general in other studies of the same age-range, should be viewed against this best feasible 88%  
3 (LEX group) outcome, rather than the best theoretical adherence of 100%.

4 There are some strengths and limitations of the current study that should be noted. A  
5 specific strength is the number of participants included in the follow up. Thirty-four (87%) of  
6 the original cohort agreed to be re-measured, which is comparable to the Johnson et al (2019)  
7 return success rate for STRRIDE (Studies of Targeted Risk Reduction Interventions through  
8 Defined Exercise) reunion study. Moreover, we have follow-up data regarding the reason for  
9 not being able to assess the remaining 10 participants, five of whom dropped out before phase  
10 B of the original study. However, an important limitation is the use of self-reported exercise at  
11 phase D rather than an objective assessment. However, given the duration of follow up,  
12 objective methods were unfeasible. Moreover, attempts to use objective measures at phase D  
13 would likely have suffered from a Hawthorn effect as others have noted (DÖSSEGGGER et al.,  
14 2014). Likewise, self-reported activity of continuation or discontinuation of exercise were only  
15 recorded on one occasion which may not be reflective of the entire follow-up period. Although,  
16 repeated measurement could have violated a true 'free-living' period by altering said  
17 behaviours. Consequently, we accepted these as limitation as an unavoidable consequence of  
18 the duration and nature of follow-up. In addition, the assessed aerobic capacity of participants  
19 was broadly commensurate with their reported levels of physical activity. Secondly, non-  
20 exercise control groups from phase A to phase D would have strengthened the conclusions of  
21 this study. However, recruiting a SED and LEX group who did not undertake the HIIT  
22 intervention was not the aim of our initial work (Knowles et al., 2015). Although non-exercise  
23 control groups would have provided additional credence to the legacy effects we propose here  
24 in, and also to ascertain whether there was a true prevention in a reduction of  $VO_{2peak}$ , the work  
25 of Rogers et al. (1990) and Johnson et al. (2019) both detail expected decreases in aerobic  
26 capacity, so the lack of  $VO_{2peak}$  loss reported here is noteworthy. While the exercise training in  
27 Phases A and B were of an aerobic nature, exercise modalities performed during the free-living  
28 period may have varied within and between participants. Accordingly, we are unable to  
29 ascertain the isolated influence from a dichotomous classification of endurance or resistance  
30 exercise types. Although, our intention was to assess cardiorespiratory fitness mediated  
31 through self-directed exercise during the free-living phase. Nonetheless, the contributions from  
32 exercise modality warrants future consideration. Furthermore, while we assessed a single,  
33 indirect marker of cardiovascular risk through cardiorespiratory fitness, we were unable to  
34 report on other clinical markers related to cardiometabolic health. Future work should consider  
35 these considering that the longer term implications of cardiorespiratory fitness and  
36 cardiometabolic parameters may be intensity dependant Johnson et al. (2019). Thus, extension  
37 of our work pertaining to low frequency, short term HIIT would be beneficial.

38 In conclusion, the addition of six weeks of HIIT following six weeks of moderate  
39 intensity exercise training increased  $VO_{2peak}$  to the extent that it was unchanged four years later  
40 in a cohort of LEX and SED older men. Thus, this combination of exercise appears a potent  
41 stimulus to increase (in the short-term) or maintain (in the long-term)  $VO_{2peak}$  in older males.  
42 The implication of these data is that exercise training concluding with 6 weeks HIIT can be  
43 utilised by practitioners and healthcare professionals to increase  $VO_{2peak}$  over a short period of  
44 time, which appears to be a catalyst for maintained cardiorespiratory fitness for years to come.  
45 There is an emergent body of evidence that endorses HIIT as an effective alternative to  
46 traditional endurance training that can yield enhancements in both cardiorespiratory fitness and  
47 a variety of health outcomes (Buchheit and Laursen, 2013; Gibala et al., 2012; Sylta et al.,  
48 2017, 2016; Yasar et al., 2019) and consequently, improvements in cardiorespiratory fitness  
49 have a significant impact on health and survival (Kaminsky et al., 2013b; Kodama et al., 2009).
